There are several other characteristics of a grammar that are sometimes useful in determining whether a grammar is ambiguous.1 They include the following: (1) if the grammar generates a sentence with more than one leftmost derivation and (2) if the grammar generates a sentence with more than one rightmost derivation.

1. Note that it is mathematically impossible to determine whether an arbitrary grammar is ambiguous.

Some parsing algorithms can be based on ambiguous grammars. When such a parser encounters an ambiguous construct, it uses nongrammatical information provided by the designer to construct the correct parse tree. In many cases, an ambiguous grammar can be rewritten to be unambiguous but still generate the desired language.

3.3.1.8 Operator Precedence

When an expression includes two different operators, for example, `x + y * z`, one obvious semantic issue is the order of evaluation of the two operators (for example, in this expression is it add and then multiply, or vice versa?). This semantic question can be answered by assigning different precedence levels to operators. For example, if `*` has been assigned higher precedence than `+` (by the language designer), multiplication will be done first, regardless of the order of appearance of the two operators in the expression.

As stated previously, a grammar can describe a certain syntactic structure so that part of the meaning of the structure can be determined from its parse tree. In particular, the fact that an operator in an arithmetic expression is generated lower in the parse tree (and therefore must be evaluated first) can be used to indicate that it has precedence over an operator produced higher up in the tree. In the first parse tree of Figure 3.2, for example, the multiplication

operator is generated lower in the tree, which could indicate that it has precedence over the addition operator in the expression. The second parse tree, however, indicates just the opposite. It appears, therefore, that the two parse trees indicate conflicting precedence information.

Notice that although the grammar of Example 3.2 is not ambiguous, the precedence order of its operators is not the usual one. In this grammar, a parse tree of a sentence with multiple operators, regardless of the particular operators involved, has the rightmost operator in the expression at the lowest point in the parse tree, with the other operators in the tree moving progressively higher as one moves to the left in the expression. For example, in the expression `A + B * C`, `*` is the lowest in the tree, indicating it is to be done first. However, in the expression `A * B + C`, `+` is the lowest, indicating it is to be done first.

A grammar can be written for the simple expressions we have been discussing that is both unambiguous and specifies a consistent precedence of the `+` and `*` operators, regardless of the order in which the operators appear in an expression. The correct ordering is specified by using separate nonterminal symbols to represent the operands of the operators that have different precedence. This requires additional nonterminals and some new rules. Instead of using <expr> for both operands of both `+` and `*`, we could use three nonterminals to represent operands, which allows the grammar to force different operators to different levels in the parse tree. If <expr> is the root symbol for expressions, `+` can be forced to the top of the parse tree by having <expr> directly generate only `+` operators, using the new nonterminal, <term>, as the right operand of `+`. Next, we can define <term> to generate `*` operators, using <term> as the left operand and a new nonterminal, <factor>, as its right operand. Now, `*` will always be lower in the parse tree, simply because it is farther from the start symbol than `+` in every derivation. The grammar of Example 3.4 is such a grammar.

EXAMPLE 3.4 An Unambiguous Grammar for Expressions

- <assign> → <id> = <expr>
- <id> → A | B | C
- <expr> → <expr> + <term>
- | <term>
- <term> → <term> * <factor>
- | <factor>
- <factor> → (<expr>)
- | <id>

The grammar in Example 3.4 generates the same language as the grammars of Examples 3.2 and 3.3, but it is unambiguous and it specifies the usual precedence order of multiplication and addition operators. The following derivation of the sentence A = B + C * A uses the grammar of Example 3.4:

- <assign> => <id> = <expr>
- => A = <expr>
- => A = <expr> + <term>
- => A = <term> + <term>
- => A = <factor> + <term>
- => A = <id> + <term>
- => A = B + <term>
- => A = B + <term> * <factor>
- => A = B + <factor> * <factor>

- => A = B + <id> * <factor>
- => A = B + C * <factor>
- => A = B + C * <id>
- => A = B + C * A

The unique parse tree for this sentence, using the grammar of Example 3.4, is shown in Figure 3.3.

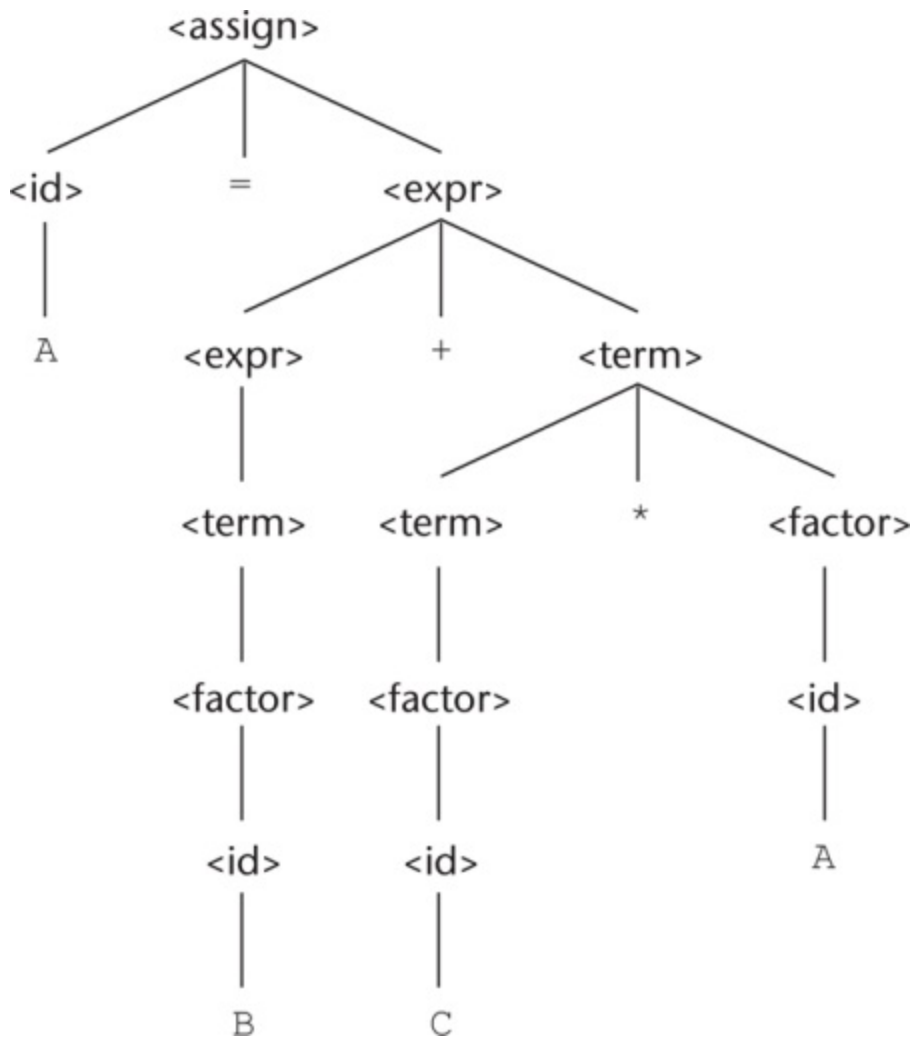

Figure 3.3 The unique parse

tree for `A = B + C * A` using an unambiguous grammar

Figure 3.3 Full Alternative Text

The connection between parse trees and derivations is very close: Either can easily be constructed from the other. Every derivation with an unambiguous grammar has a unique parse tree, although that tree can be represented by different derivations. For example, the following derivation of the sentence `A = B + C * A` is different from the derivation of the same sentence given previously. This is a rightmost derivation, whereas the previous one is leftmost. Both of these derivations, however, are represented by the same parse tree.

- <assign> => <id> = <expr>
- => <id> = <expr> + <term>
- => <id> = <expr> + <term> * <factor>
- => <id> = <expr> + <term> * <id>
- => <id> = <expr> + <term> * A
- => <id> = <expr> + <factor> * A
- => <id> = <expr> + <id> * A
- => <id> = <expr> + C * A
- => <id> = <term> + C * A
- => <id> = <factor> + C * A
- => <id> = <id> + C * A

- => <id> = B + C * A
- => A = B + C * A

3.3.1.9 Associativity of Operators

When an expression includes two operators that have the same precedence (as * and / usually have)—for example, A / B * C—a semantic rule is required to specify which should have precedence.2 This rule is named *associativity*.

2. An expression with two occurrences of the same operator has the same issue; for example, A / B / C.

As was the case with precedence, a grammar for expressions may correctly imply operator associativity. Consider the following example of an assignment statement:

```
A = B + C + A
```

The parse tree for this sentence, as defined with the grammar of Example 3.4, is shown in Figure 3.4.

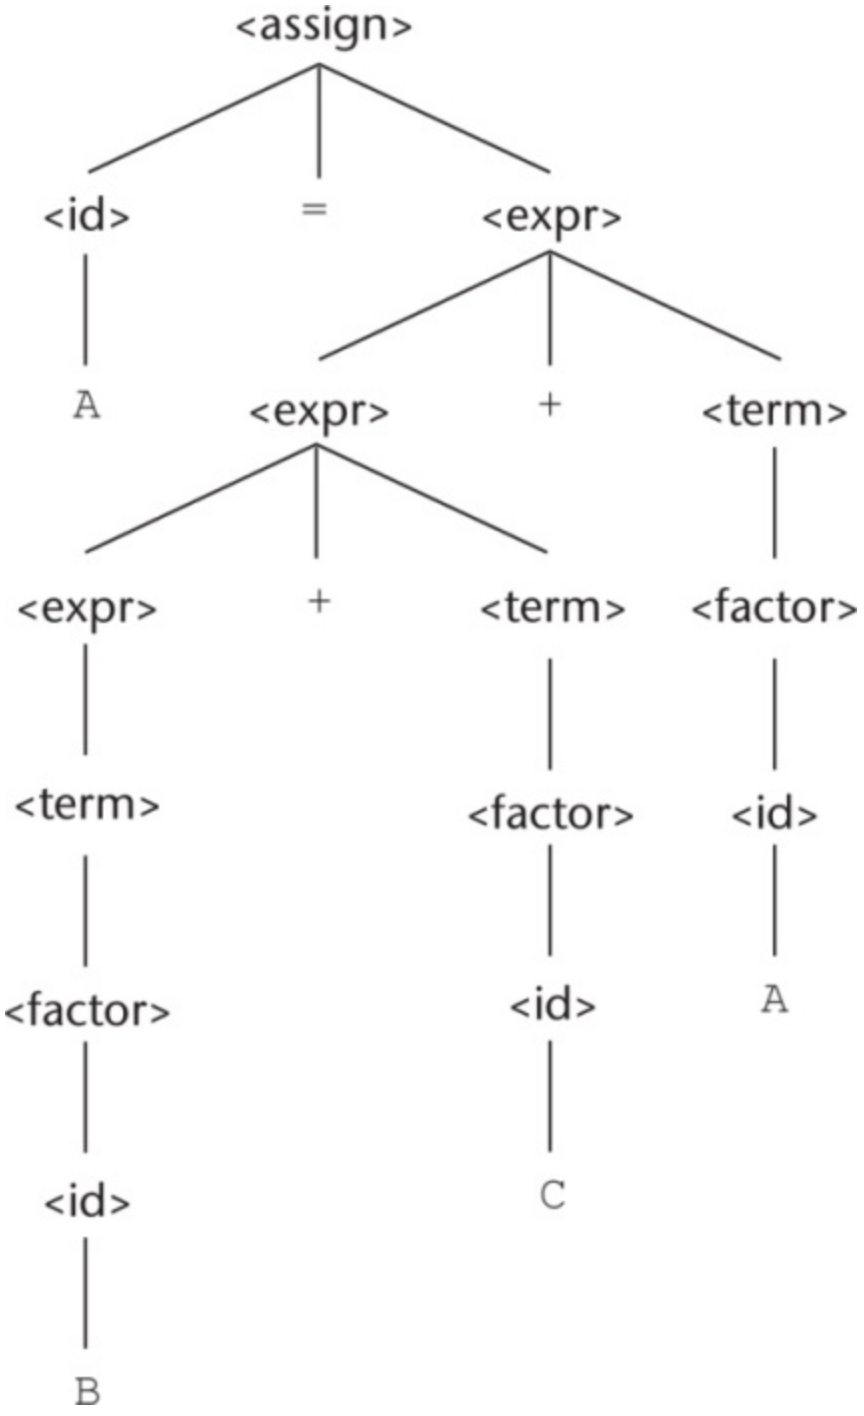

Figure 3.4 A parse tree for `A = B + C + A` illustrating the

associativity of addition

Figure 3.4 Full Alternative Text

The parse tree of Figure 3.4 shows the left addition operator lower than the right addition operator. This is the correct order if addition is meant to be left associative, which is typical. In most cases, the associativity of addition in a computer is irrelevant. In mathematics, addition is associative, which means that left and right associative orders of evaluation mean the same thing. That is, `(A + B) + C = A + (B + C)`. Floating-point addition in a computer, however, is not necessarily associative. For example, suppose floating-point values store seven digits of accuracy. Consider the problem of adding 11 numbers together, where one of the numbers is 107 and the other ten are 1. If the small numbers (the 1's) are each added to the large number, one at a time, there is no effect on that number, because the small numbers occur in the eighth digit of the large number. However, if the small numbers are first added together and the result is added to the large number, the result in seven-digit accuracy is 1.000001 * 107. Subtraction and division are not associative, whether in mathematics or in a computer. Therefore, correct associativity may be essential for an expression that contains either of them.

When a grammar rule has its LHS also appearing at the beginning of its RHS, the rule is said to be **left recursive**. This left recursion specifies left associativity. For example, the left recursion of the rules of the grammar of Example 3.4 causes it to make both addition and multiplication left associative. Unfortunately, left recursion disallows the use of some important syntax analysis algorithms. When one of these algorithms is to be used, the grammar must be modified to remove the left recursion. This, in turn, disallows the grammar from precisely specifying that certain operators are left associative. Fortunately, left associativity can be enforced by the compiler, even though the grammar does not dictate it.

In most languages that provide it, the exponentiation operator is right associative. To indicate right associativity, right recursion can be used. A grammar rule is **right recursive** if the LHS appears at the right end of the RHS. Rules such as

- <factor> → <exp> ** <factor>
- |<exp>
- <exp> → (<expr>)
- |id

could be used to describe exponentiation as a right-associative operator.

3.3.1.10 An Unambiguous Grammar for `if-else`

The BNF rules for a Java **`if-else`** statement are as follows:

- <if_stmt> → **`if`** (<logic_expr>) <stmt>
- **`if`** (<logic_expr>) <stmt> **`else`** <stmt>

If we also have <stmt> → <if_stmt>, this grammar is ambiguous. The simplest sentential form that illustrates this ambiguity is

- **`if`** (<logic_expr>) **`if`** (<logic_expr>) <stmt> **`else`** <stmt>

The two parse trees in Figure 3.5 show the ambiguity of this sentential form. Consider the following example of this construct:

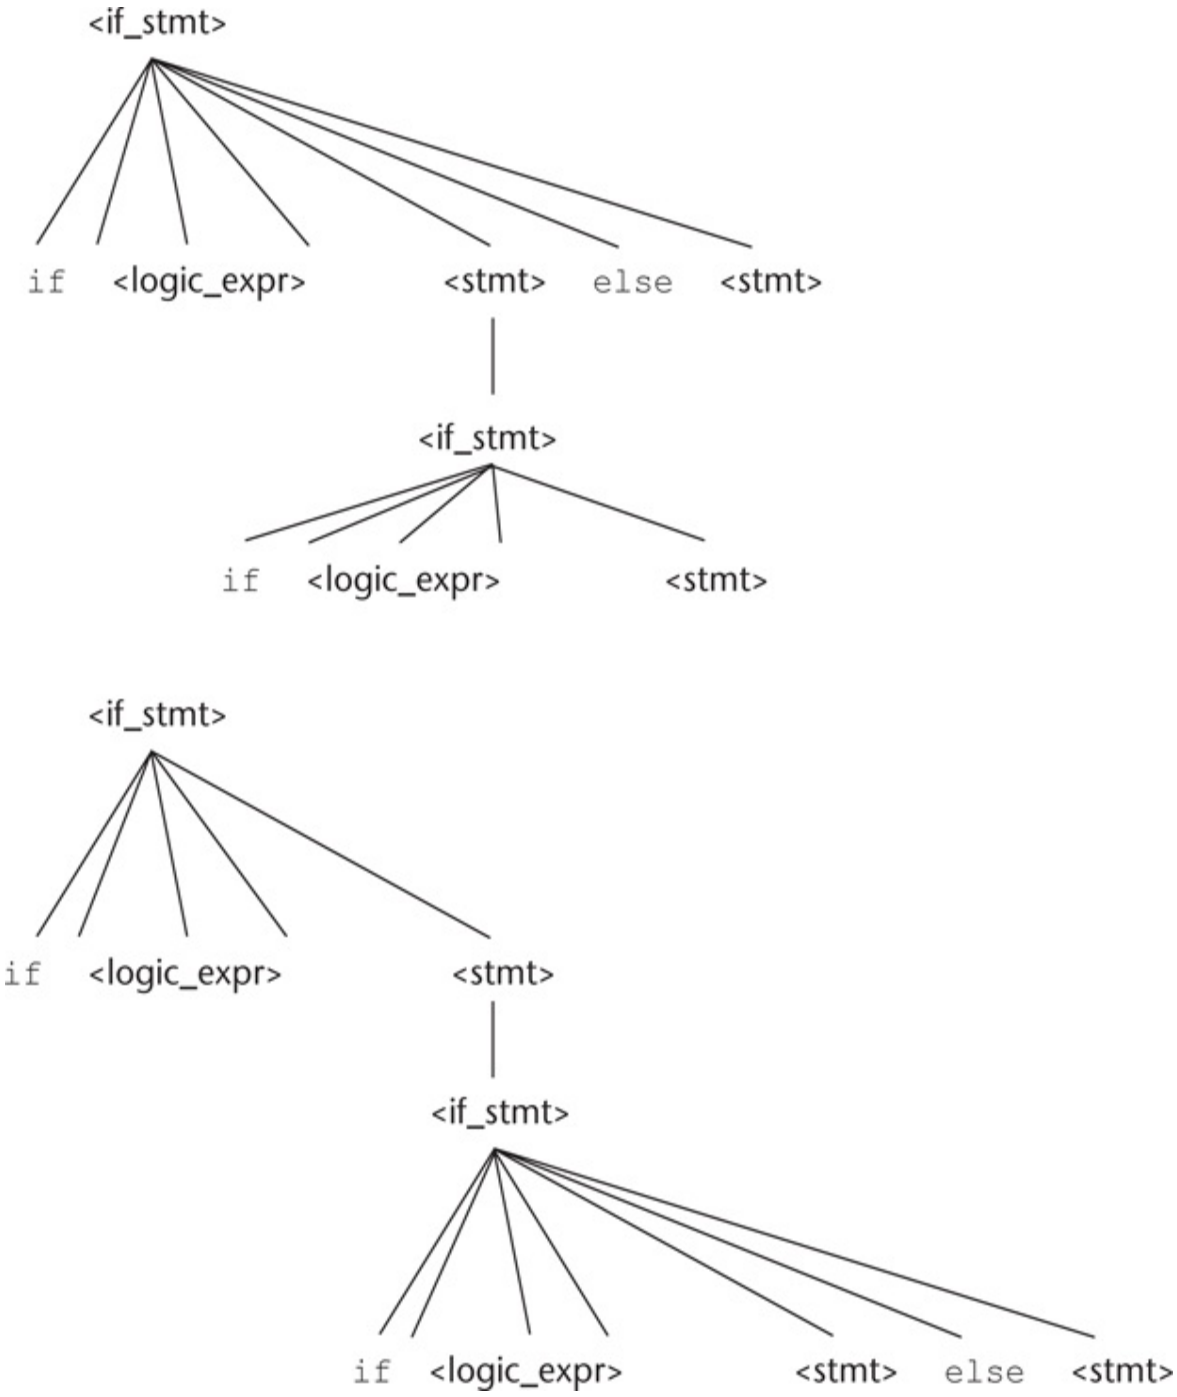

Figure 3.5 Two distinct parse trees for the same sentential form

Figure 3.5 Full Alternative Text

- `if (done == true)`
- `if (denom == 0)`
- `    quotient = 0;`
- `    else quotient = num / denom;`

The problem is that if the upper parse tree in Figure 3.5 is used as the basis for translation, the else clause would be executed when `done` is not true, which probably is not what was intended by the author of the construct. We will examine the practical problems associated with this else-association problem in Chapter 8.

We will now develop an unambiguous grammar that describes this **`if`** statement. The rule for **`if`** constructs in many languages is that an else clause, when present, is matched with the nearest previous unmatched then clause. Therefore, there cannot be an **`if`** statement without an **`else`** between a then clause and its matching **`else`**. So, for this situation, statements must be distinguished between those that are matched and those that are unmatched, where unmatched statements are **`else`**-less **`if`**s and all other statements are matched. The problem with the earlier grammar is that it treats all statements as if they had equal syntactic significance—that is, as if they were all matched.

To reflect the different categories of statements, different abstractions, or nonterminals, must be used. The unambiguous grammar based on these ideas follows:

- <stmt> → <matched> | <unmatched>
- <matched> → **`if`** (<logic_expr>) <matched> **`else`** <matched>
- |any non-if statement
- <unmatched> → **`if`** (<logic_expr>) <stmt>

- |**if** (<logic_expr>) <matched> **else** <unmatched>

There is just one possible parse tree, using this grammar, for the following sentential form:

- **if** (<logic_expr>) **if** (<logic_expr>) <stmt> **else** <stmt>

3.3.2 Extended BNF

Because of a few minor inconveniences in BNF, it has been extended in several ways. Most extended versions are called Extended BNF, or simply EBNF, even though they are not all exactly the same. The extensions do not enhance the descriptive power of BNF; they only increase its readability and writability.

Three extensions are commonly included in the various versions of EBNF. The first of these denotes an optional part of an RHS, which is delimited by brackets. For example, a C **if-else** statement can be described as

- <if_stmt> → **if** (<expression>) <statement> [**else** <statement>]

Without the use of the brackets, the syntactic description of this statement would require the following two rules:

- <if_stmt> → **if** (<expression>) <statement>
- |**if** (<expression>) <statement> **else** <statement>

The second extension is the use of braces in a RHS to indicate that the enclosed part can be repeated indefinitely or left out altogether. This extension allows lists to be built with a single rule, instead of using recursion and two rules. For example, lists of identifiers separated by commas can be described by the following rule:

- <ident_list> → <identifier> {, <identifier>}

This is a replacement of the recursion by a form of implied iteration; the part

enclosed within braces can be iterated any number of times.

The third common extension deals with multiple-choice options. When a single element must be chosen from a group, the options are placed in parentheses and separated by the OR operator, `|`. For example,

- <term> → <term> (`*` | `/` | `%`) <factor>

In BNF, a description of this <term> would require the following three rules:

- <term> → <term> `*` <factor>
- | <term> `/` <factor>
- | <term> `%` <factor>

The brackets, braces, and parentheses in the EBNF extensions are **metasymbols**, which means they are notational tools and not terminal symbols in the syntactic entities they help describe. In cases where these metasymbols are also terminal symbols in the language being described, the instances that are terminal symbols can be underlined or quoted. Example 3.5 illustrates the use of braces and multiple choices in an EBNF grammar.

EXAMPLE 3.5 BNF and EBNF Versions of an Expression Grammar

BNF:

- <expr> → <expr> + <term>
- | <expr> - <term>
- | <term>

- <term> → <term> * <factor>
- | <term> / <factor>
- | <factor>
- <factor> → <exp> ** <factor>
- <exp>
- <exp> → (<expr>)
- | id

EBNF:

- <expr> → <term> {(+ | -) <term>}
- <term> → <factor> {(* | /) <factor>}
- <factor> → <exp> { ** <exp>}
- <exp> → (<expr>)
- | id

The BNF rule

- <expr> → <expr> + <term>

clearly specifies—in fact forces—the + operator to be left associative. However, the EBNF version,

- <expr> → <term> {+ <term>}

does not imply the direction of associativity. This problem is overcome in a syntax analyzer based on an EBNF grammar for expressions by designing the syntax analysis process to enforce the correct associativity. This is discussed further in Chapter 4.

Some versions of EBNF allow a numeric superscript to be attached to the right brace to indicate an upper limit to the number of times the enclosed part can be repeated. Also, some versions use a plus (+) superscript to indicate one or more repetitions. For example,

- <compound> → **`begin`** <stmt> `{`<stmt>`}` **`end`**

and

- <compound> → **`begin`** `{`<stmt>`}`$^{+}$ **`end`**

are equivalent.

In recent years, some variations on BNF and EBNF have appeared. Among these are the following:

- In place of the arrow, a colon is used and the RHS is placed on the next line.
- Instead of a vertical bar to separate alternative RHSs, they are simply placed on separate lines.
- In place of square brackets to indicate something being optional, the subscript opt is used. For example,
- Constructor Declarator → SimpleName (FormalParameterListopt)
- Rather than using the `|` symbol in a parenthesized list of elements to indicate a choice, the words “one of” are used. For example,
    - AssignmentOperator → one of `= *= /= %= += -=`
    - `<<= >>= &= ^= |=`

There is a standard for EBNF, ISO/IEC 14977:1996 (1996), but it is rarely used. The standard uses the equal sign (=) instead of an arrow in rules, terminates each RHS with a semicolon, and requires quotes on all terminal symbols. It also specifies a host of other notational rules.

3.3.3 Grammars and Recognizers

Earlier in this chapter, we suggested that there is a close relationship between generation and recognition devices for a given language. In fact, given a - context-free grammar, a recognizer for the language generated by the grammar can be algorithmically constructed. A number of software systems have been developed that perform this construction. Such systems allow the quick creation of the syntax analysis part of a compiler for a new language and are therefore quite valuable. One of the first of these syntax analyzer generators is named yacc (*y*et *a*nother *c*ompiler *c*ompiler) (Johnson, 1975). There are now many such systems available.

3.4 Attribute Grammars

An **attribute grammar** is a device used to describe more of the structure of a programming language than can be described with a context-free grammar. An attribute grammar is an extension to a context-free grammar. The extension allows certain language rules to be conveniently described, such as type compatibility. Before we formally define the form of attribute grammars, we must clarify the concept of static semantics.

history note

Attribute grammars have been used in a wide variety of applications. They have been used to provide complete descriptions of the syntax and static semantics of programming languages (Watt, 1979); they have been used as the formal definition of a language that can be input to a compiler generation system (Farrow, 1982); and they have been used as the basis of several syntax-directed editing systems (Teitelbaum and Reps, 1981; Fischer et al., 1984). In addition, attribute grammars have been used in natural-language processing systems (Correa, 1992).

3.4.1 Static Semantics

There are some characteristics of programming languages that are difficult to describe with BNF, and some that are impossible. As an example of a syntax rule that is difficult to specify with BNF, consider type compatibility rules. In Java, for example, a floating-point value cannot be assigned to an integer type variable, although the opposite is legal. Although this restriction can be specified in BNF, it requires additional nonterminal symbols and rules. If all of the typing rules of Java were specified in BNF, the grammar would become too large to be useful, because the size of the grammar determines the size of the syntax analyzer.

As an example of a syntax rule that cannot be specified in BNF, consider the common rule that all variables must be declared before they are referenced. It has been proven that this rule cannot be specified in BNF.

These problems exemplify the categories of language rules called static semantics rules. The **static semantics** of a language is only indirectly related to the meaning of programs during execution; rather, it has to do with the legal forms of programs (syntax rather than semantics). Many static semantic rules of a language state its type constraints. Static semantics is so named because the analysis required to check these specifications can be done at compile time.

Because of the problems of describing static semantics with BNF, a variety of more powerful mechanisms has been devised for that task. One such mechanism, attribute grammars, was designed by Knuth (1968) to describe both the syntax and the static semantics of programs.

Attribute grammars are a formal approach both to describing and checking the correctness of the static semantics rules of a program. Although they are not always used in a formal way in compiler design, the basic concepts of attribute grammars are at least informally used in every compiler (see Aho et al., 1988).

Dynamic semantics, which is the meaning of expressions, statements, and program units, is discussed in Section 3.5.

3.4.2 Basic Concepts

Attribute grammars are context-free grammars to which have been added attributes, attribute computation functions, and predicate functions. **Attributes**, which are associated with grammar symbols (the terminal and nonterminal symbols), are similar to variables in the sense that they can have values assigned to them. **Attribute computation functions**, sometimes called semantic functions, are associated with grammar rules. They are used to specify how attribute values are computed. **Predicate functions**, which state the static semantic rules of the language, are associated with grammar

rules.

These concepts will become clearer after we formally define attribute grammars and provide an example.

3.4.3 Attribute Grammars Defined

An attribute grammar is a grammar with the following additional features:

- Associated with each grammar symbol X is a set of attributes A(X). The set A(X) consists of two disjoint sets S(X) and I(X), called synthesized and inherited attributes, respectively. **Synthesized attributes** are used to pass semantic information up a parse tree, while **inherited attributes** pass semantic information down and across a tree.

- Associated with each grammar rule is a set of semantic functions and a possibly empty set of predicate functions over the attributes of the symbols in the grammar rule. For a rule the $X0 \rightarrow X1 \ldots Xn$, synthesized attributes of X0 are computed with semantic functions of the form S(X0)=f(A(X1), …, A(Xn)). So the value of a synthesized attribute on a parse tree node depends only on the values of the attributes on that node's children nodes. Inherited attributes of symbols Xj, $1 \leq j \leq n$ (in the rule above), are computed with a semantic function of the form I(Xj=f(A(X0), …, A(Xn)). So the value of an inherited attribute on a parse tree node depends on the attribute values of that node's parent node and those of its sibling nodes. Note that, to avoid circularity, inherited attributes are often restricted to functions of the form I(Xj)=f(A(X0), …, A(X(_{j−1}))). This form prevents an inherited attribute from depending on itself or on attributes to the right in the parse tree.

- A predicate function has the form of a Boolean expression on the union of the attribute set {A(X0), …, A(Xn)} and a set of literal attribute values. The only derivations allowed with an attribute grammar are those in which every predicate associated with every nonterminal is true. A false predicate function value indicates a violation of the syntax or

static semantics rules of the language.

A parse tree of an attribute grammar is the parse tree based on its underlying BNF grammar, with a possibly empty set of attribute values attached to each node. If all the attribute values in a parse tree have been computed, the tree is said to be **fully attributed**. Although in practice it is not always done this way, it is convenient to think of attribute values as being computed after the complete unattributed parse tree has been constructed by the compiler.

3.4.4 Intrinsic Attributes

Intrinsic attributes are synthesized attributes of leaf nodes whose values are determined outside the parse tree. For example, the type of an instance of a variable in a program could come from the symbol table, which is used to store variable names and their types. The contents of the symbol table are set based on earlier declaration statements. Initially, assuming that an unattributed parse tree has been constructed and that attribute values are needed, the only attributes with values are the intrinsic attributes of the leaf nodes. Given the intrinsic attribute values on a parse tree, the semantic functions can be used to compute the remaining attribute values.

3.4.5 Examples of Attribute Grammars

As a very simple example of how attribute grammars can be used to describe static semantics, consider the following fragment of an attribute grammar that describes the rule that the name on the **`end`** of an Ada procedure must match the procedure's name. (This rule cannot be stated in BNF.) The string attribute of <proc_name>, denoted by <proc_name>.string, is the actual string of characters that were found immediately following the reserved word **`procedure`** by the compiler. Notice that when there is more than one occurrence of a nonterminal in a syntax rule in an attribute grammar, the nonterminals are subscripted with brackets to distinguish them. Neither the

subscripts nor the brackets are part of the described language.

- Syntax rule: <proc_def> → **`procedure`** <proc_name>`[1]`
- <proc_body> **`end`** <proc_name>`[2];`
- Predicate: <proc_name>`[1]`string == <proc_name>`[2]`.string

In this example, the predicate rule states that the name string attribute of the <proc_name> nonterminal in the subprogram header must match the name string attribute of the <proc_name> nonterminal following the end of the subprogram.

Next, we consider a larger example of an attribute grammar. In this case, the example illustrates how an attribute grammar can be used to check the type rules of a simple assignment statement. The syntax and static semantics of this assignment statement are as follows: The only variable names are `A`, `B`, and `C`. The right side of the assignments can be either a variable or an expression in the form of a variable added to another variable. The variables can be one of two types: int or real. When there are two variables on the right side of an assignment, they need not be the same type. The type of the expression when the operand types are not the same is always real. When they are the same, the expression type is that of the operands. The type of the left side of the assignment must match the type of the right side. So the types of operands in the right side can be mixed, but the assignment is valid only if the target and the value resulting from evaluating the right side have the same type. The attribute grammar specifies these static semantic rules.

The syntax portion of our example attribute grammar is

- <assign> → <var> = <expr>
- <expr> → <var> + <var>
- | <var>
- <var> → `A | B | C`

The attributes for the nonterminals in the example attribute grammar are

described in the following paragraphs:

- actual_type—A synthesized attribute associated with the nonterminals <var> and <expr>. It is used to store the actual type, int or real, of a variable or expression. In the case of a variable, the actual type is intrinsic. In the case of an expression, it is determined from the actual types of the child node or children nodes of the <expr> nonterminal.

- expected_type—An inherited attribute associated with the nonterminal <expr>. It is used to store the type, either int or real, that is expected for the expression, as determined by the type of the variable on the left side of the assignment statement.

  The complete attribute grammar follows in Example 3.6.

EXAMPLE 3.6 An Attribute Grammar for Simple Assignment Statements

1. Syntax rule: <assign> → <var> = <expr>

   Semantic rule: <expr>.expected_type ← <var>.actual_type

2. Syntax rule: <expr> → <var>[2] + <var>[3]

   Semantic rule: <expr>.actual_type ←

   if (<var>[2].actual_type = int) and

   (<var>[3].actual_type = int)

   then int

   else real

end if

Predicate: <expr>.actual_type == <expr>.expected_type

3. Syntax rule: <expr> → <var>

   Semantic rule: <expr>.actual_type ← <var>.actual_type

   Predicate: <expr>.actual_type == <expr>.expected_type

4. Syntax rule: <var> → `A | B | C`

   Semantic rule: <var>.actual_type ← look-up(<var>.string)

The look-up function looks up a given variable name in the symbol table and returns the variable's type.

A parse tree of the sentence `A = A + B` generated by the grammar in Example 3.6 is shown in Figure 3.6. As in the grammar, bracketed numbers are added after the repeated node labels in the tree so they can be referenced unambiguously.

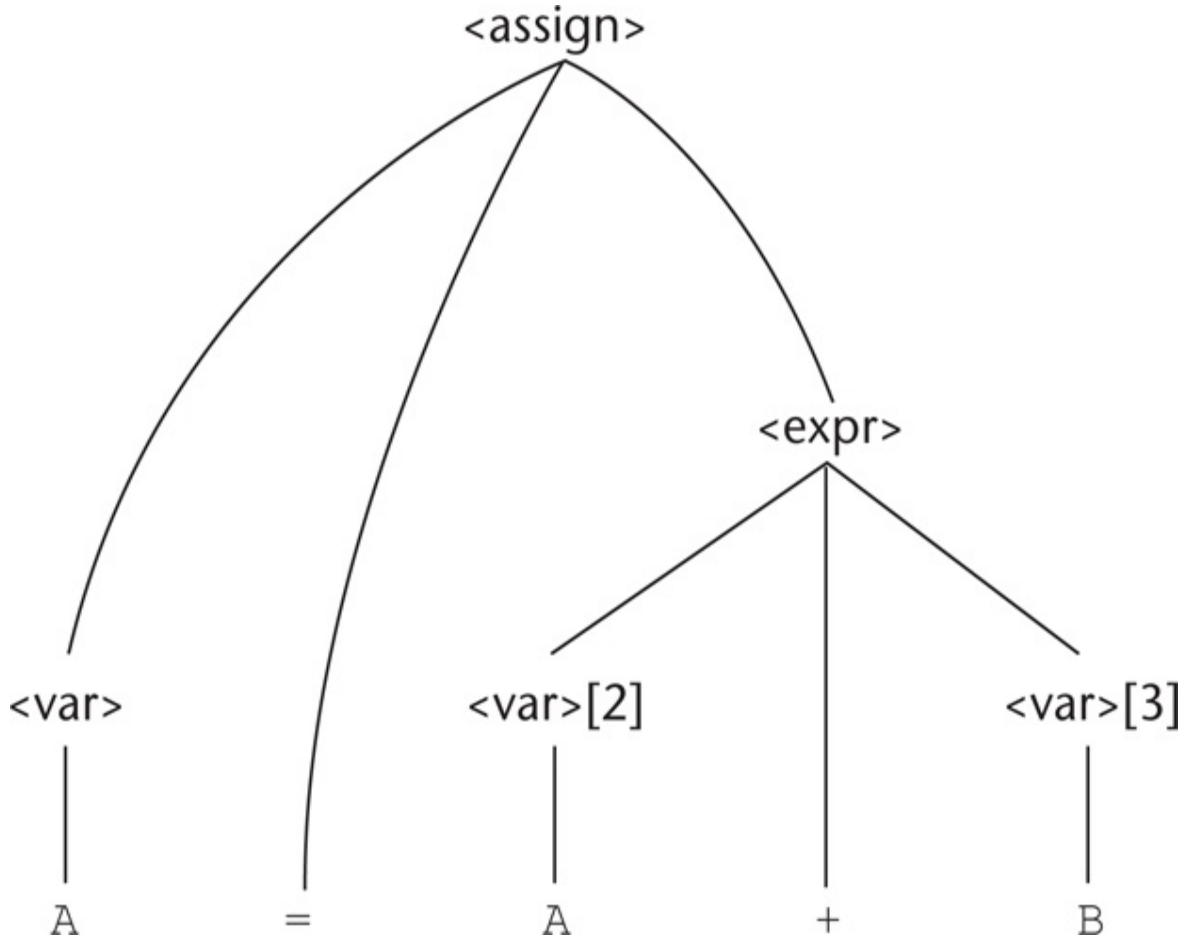

Figure 3.6 A parse tree for `A = A + B`

Figure 3.6 Full Alternative Text

3.4.6 Computing Attribute Values

Now, consider the process of computing the attribute values of a parse tree, which is sometimes called **decorating** the parse tree. If all attributes were inherited, this could proceed in a completely top-down order, from the root to the leaves. Alternatively, it could proceed in a completely bottom-up order, from the leaves to the root, if all the attributes were synthesized. Because our

grammar has both synthesized and inherited attributes, the evaluation process cannot be in any single direction. The following is an evaluation of the attributes, in an order in which it is possible to compute them:

1. <var>.actual_type ← look-up(A) (Rule 4)
2. <expr>.expected_type ← <var>.actual_type (Rule 1)
3. <var>[2].actual_type ← look-up(A) (Rule 4)

   <var>[3].actual_type ← look-up(B) (Rule 4)
4. <expr>.actual_type ← either int or real (Rule 2)
5. <expr>.expected_type == <expr>.actual_type is either

   TRUE or FALSE (Rule 2)

The tree in Figure 3.7 shows the flow of attribute values in the example of Figure 3.6. Solid lines show the parse tree; dashed lines show attribute flow in the tree.

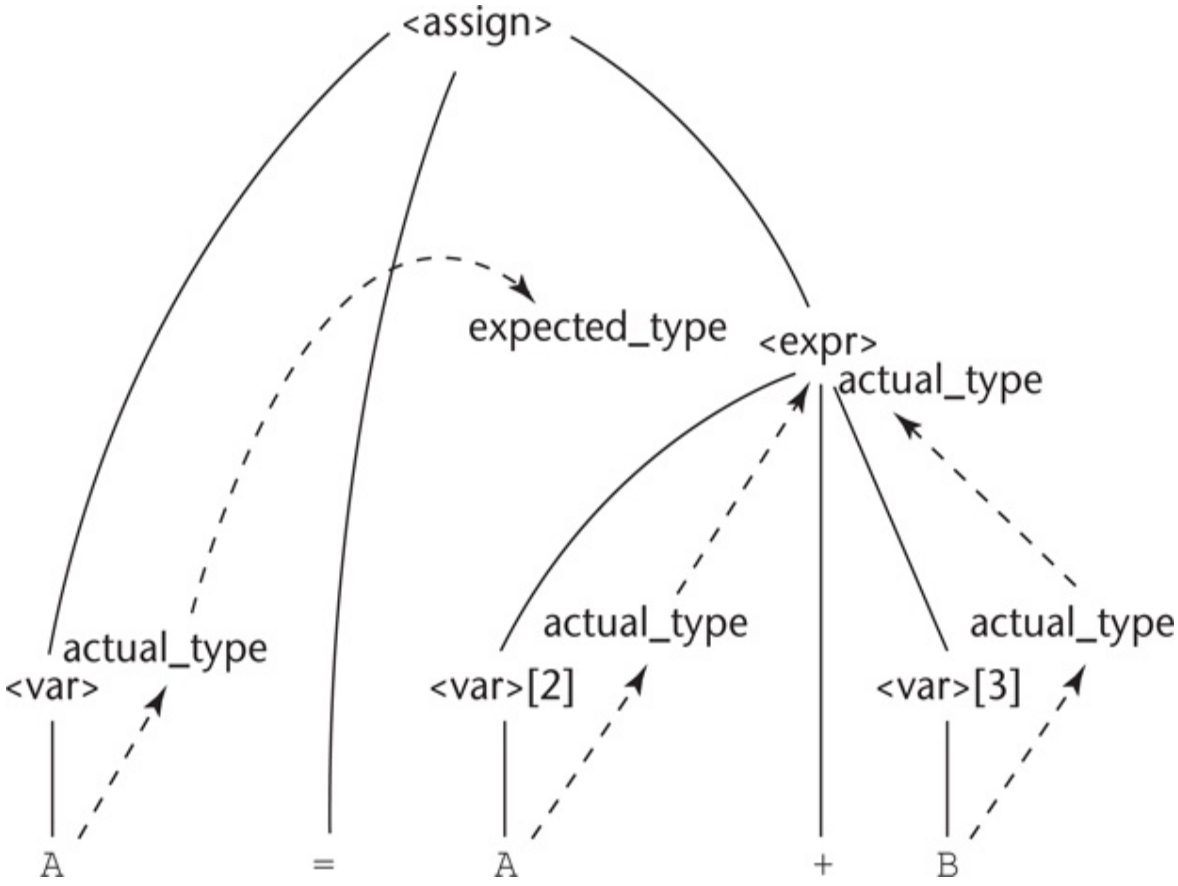

Figure 3.7 The flow of attributes in the tree

Figure 3.7 Full Alternative Text

The tree in Figure 3.8 shows the final attribute values on the nodes. In this example, A is defined as a real and B is defined as an int.

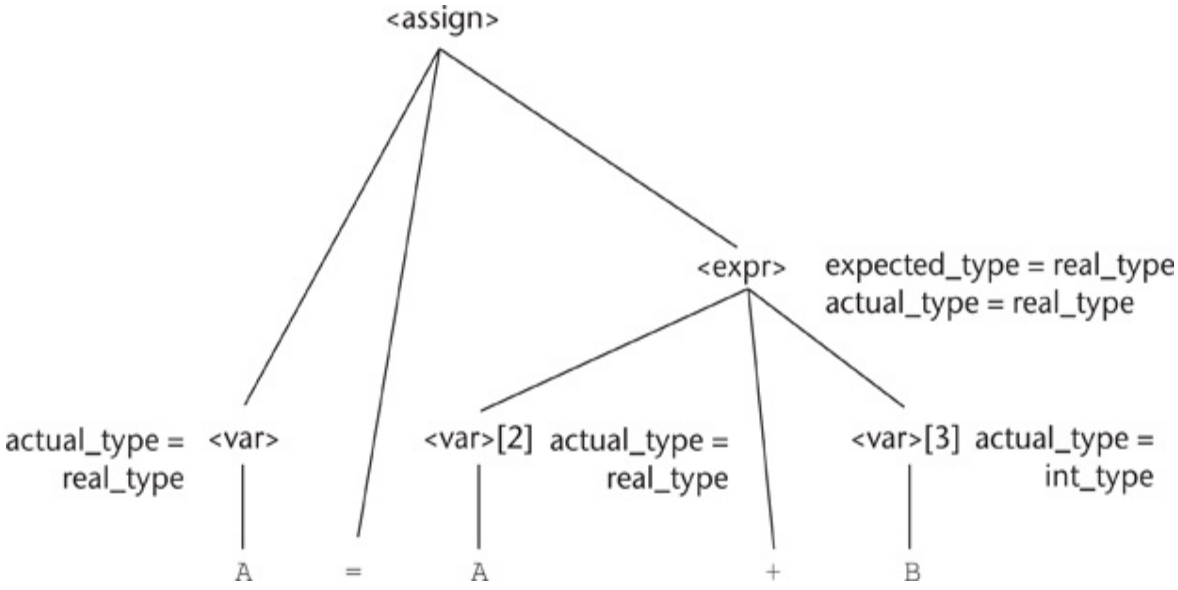

Figure 3.8 A fully attributed parse tree

Figure 3.8 Full Alternative Text

Determining attribute evaluation order for the general case of an attribute grammar is a complex problem, requiring the construction of a dependency graph to show all attribute dependencies.

3.4.7 Evaluation

Checking the static semantic rules of a language is an essential part of all compilers. Even if a compiler writer has never heard of an attribute grammar, he or she would need to use the fundamental ideas of attribute grammars to design the checks of static semantics rules for his or her compiler.

One of the main difficulties in using an attribute grammar to describe all of the syntax and static semantics of a real contemporary programming - language is the size and complexity of the attribute grammar. The large number of attributes and semantic rules required for a complete programming

language make such grammars difficult to write and read. Furthermore, the attribute values on a large parse tree are costly to evaluate. On the other hand, less formal attribute grammars are a powerful and commonly used tool for compiler writers, who are more interested in the process of producing a compiler than they are in formalism.

3.5 Describing the Meanings of Programs: Dynamic Semantics

We now turn to the difficult task of describing the **dynamic semantics**, or meaning, of the expressions, statements, and program units of a programming language. Because of the power and naturalness of the available notation, describing syntax is a relatively simple matter. On the other hand, no universally accepted notation or approach has been devised for dynamic semantics. In this section, we briefly describe several of the methods that have been developed. For the remainder of this section, when we use the term *semantics*, we mean dynamic semantics.

There are several different reasons underlying the need for a methodology and notation for describing semantics. Programmers obviously need to know precisely what the statements of a language do before they can use them effectively in their programs. Compiler writers must know exactly what language constructs mean to design implementations for them correctly. If there were a precise semantics specification of a programming language, programs written in the language potentially could be proven correct without testing. Also, compilers could be shown to produce programs that exhibited exactly the behavior given in the language definition; that is, their correctness could be verified. A complete specification of the syntax and semantics of a programming language could be used by a tool to generate a compiler for the language automatically. Finally, language designers, who would develop the semantic descriptions of their languages, could in the process discover ambiguities and inconsistencies in their designs.

Software developers and compiler designers typically determine the semantics of programming languages by reading English explanations in language manuals. Because such explanations are often imprecise and incomplete, this approach is clearly unsatisfactory. Due to the lack of complete semantics specifications of programming languages, programs are rarely proven correct without testing, and commercial compilers are never generated automatically from language descriptions.

Scheme, a functional language described in Chapter 15, is one of only a few programming languages whose definition includes a formal semantics description. However, the method used is not one described in this chapter, as this chapter is focused on approaches that are suitable for imperative languages.

3.5.1 Operational Semantics

The idea behind **operational semantics** is to describe the meaning of a statement or program by specifying the effects of running it on a machine. The effects on the machine are viewed as the sequence of changes in its state, where the machine's state is the collection of the values in its storage. An obvious operational semantics description, then, is given by executing a compiled version of the program on a computer. Most programmers have, on at least one occasion, written a small test program to determine the meaning of some programming language construct, often while learning the language. Essentially, what such a programmer is doing is using operational semantics to determine the meaning of the construct.

There are several problems with using this approach for complete formal semantics descriptions. First, the individual steps in the execution of machine language and the resulting changes to the state of the machine are too small and too numerous. Second, the storage of a real computer is too large and complex. There are usually several levels of memory devices, as well as connections to enumerable other computers and memory devices through networks. Therefore, machine languages and real computers are not used for formal operational semantics. Rather, intermediate-level languages and interpreters for idealized computers are designed specifically for the process.

There are different levels of uses of operational semantics. At the highest level, the interest is in the final result of the execution of a complete program. This is sometimes called **natural operational semantics**. At the lowest level, operational semantics can be used to determine the precise meaning of a program through an examination of the complete sequence of state changes that occur when the program is executed. This use is sometimes called **structural operational semantics**.

3.5.1.1 The Basic Process

The first step in creating an operational semantics description of a language is to design an appropriate intermediate language, where the primary desired characteristic of the language is clarity. Every construct of the intermediate language must have an obvious and unambiguous meaning. This language is at the intermediate level, because machine language is too low-level to be easily understood and another high-level language is obviously not suitable. If the semantics description is to be used for natural operational semantics, a virtual machine (an interpreter) must be constructed for the intermediate language. The virtual machine can be used to execute either single statements, code segments, or whole programs. The semantics description can be used without a virtual machine if the meaning of a single statement is all that is required. In this use, which is structural operational semantics, the intermediate code can be visually inspected.

The basic process of operational semantics is not unusual. In fact, the concept is frequently used in programming textbooks and programming language reference manuals. For example, the semantics of the C `for` construct can be described in terms of simpler statements, as in

C Statement	*Meaning*

`for (expr1; expr2; expr3) {`
`  ...`
`}`
	`expr1;`
	`loop: if expr2 == 0 goto out`
	`...`
	`expr3;`
	`goto loop`
	`out: ...`

The human reader of such a description is the virtual computer and is assumed to be able to “execute” the instructions in the definition correctly and recognize the effects of the “execution.”

The intermediate language and its associated virtual machine used for formal operational semantics descriptions are often highly abstract. The intermediate

language is meant to be convenient for the virtual machine, rather than for human readers. For our purposes, however, a more human-oriented intermediate language could be used. As such an example, consider the following list of statements, which would be adequate for describing the semantics of the simple control statements of a typical programming language:

- ident = var
- ident = ident + 1
- ident = ident – 1
- **`goto`** label
- **`if`** var relop var **`goto`** label

In these statements, relop is one of the relational operators from the set `{=, <>, >, <, <=, <=}`, ident is an identifier, and var is either an identifier or a constant. These statements are all simple and therefore easy to understand and implement.

A slight generalization of these three assignment statements allows more general arithmetic expressions and assignment statements to be described. The new statements are

- ident = var bin_op var
- ident = un_op var

where bin_op is a binary arithmetic operator and un_op is a unary operator. Multiple arithmetic data types and automatic type conversions, of course, complicate this generalization. Adding just a few more relatively simple instructions would allow the semantics of arrays, records, pointers, and subprograms to be described.

In Chapter 8, the semantics of various control statements are described using this intermediate language.

3.5.1.2 Evaluation

The first and most significant use of formal operational semantics was to describe the semantics of PL/I (Wegner, 1972). That particular abstract machine and the translation rules for PL/I were together named the Vienna Definition Language (VDL), after the city where IBM designed it.

Operational semantics provides an effective means of describing semantics for language users and language implementors, as long as the descriptions are kept simple and informal. The VDL description of PL/I, unfortunately, is so complex that it serves no practical purpose.

Operational semantics depends on programming languages of lower levels, not mathematics. The statements of one programming language are described in terms of the statements of a lower-level programming language. This approach can lead to circularities, in which concepts are indirectly defined in terms of themselves. The methods described in the following two sections are much more formal, in the sense that they are based on mathematics and logic, not programming languages.

3.5.2 Denotational Semantics

Denotational semantics is the most rigorous and most widely known formal method for describing the meaning of programs. It is solidly based on recursive function theory. A thorough discussion of the use of denotational semantics to describe the semantics of programming languages is necessarily long and complex. It is our intent to provide the reader with an introduction to the central concepts of denotational semantics, along with a few simple examples that are relevant to programming language specifications.

The process of constructing a denotational semantics specification for a programming language requires one to define for each language entity both a mathematical object and a function that maps instances of that language entity onto instances of the mathematical object. Because the objects are rigorously defined, they model the exact meaning of their corresponding

entities. The idea is based on the fact that there are rigorous ways of manipulating mathematical objects but not programming language constructs. The difficulty with this method lies in creating the objects and the mapping functions. The method is named *denotational* because the mathematical objects denote the meaning of their corresponding syntactic entities.

The mapping functions of a denotational semantics programming language specification, like all functions in mathematics, have a domain and a range. The domain is the collection of values that are legitimate parameters to the function; the range is the collection of objects to which the parameters are mapped. In denotational semantics, the domain is called the **syntactic domain**, because it is syntactic structures that are mapped. The range is called the **semantic domain**.

Denotational semantics is related to operational semantics. In operational semantics, programming language constructs are translated into simpler programming language constructs, which become the basis of the meaning of the construct. In denotational semantics, programming language constructs are mapped to mathematical objects, either sets or, more often, functions. However, unlike operational semantics, denotational semantics does not model the step-by-step computational processing of programs.

3.5.2.1 Two Simple Examples

We use a very simple language construct, character string representations of binary numbers, to introduce the denotational method. The syntax of such binary numbers can be described by the following grammar rules:

- <bin_num> → `'0'`
- | `'1'`
- | <bin_num> `'0'`
- | <bin_num> `'1'`

A parse tree for the example binary number, `110`, is shown in Figure 3.9.

Notice that we put apostrophes around the syntactic digits to show they are not mathematical digits. This is similar to the relationship between ASCII coded digits and mathematical digits. When a program reads a number as a string, it must be converted to a mathematical number before it can be used as a value in the program.

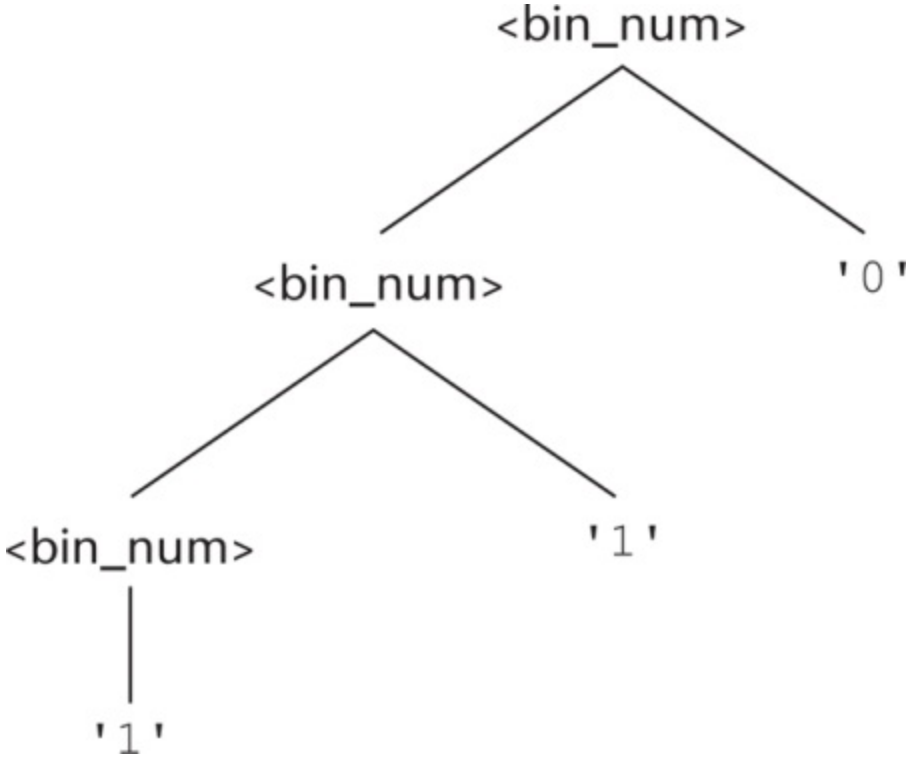

Figure 3.9 A parse tree of the binary number 110

Figure 3.9 Full Alternative Text

The syntactic domain of the mapping function for binary numbers is the set of all character string representations of binary numbers. The semantic domain is the set of nonnegative decimal numbers, symbolized by N.

To describe the meaning of binary numbers using denotational semantics, we associate the actual meaning (a decimal number) with each rule that has a single terminal symbol as its RHS.

In our example, decimal numbers must be associated with the first two grammar rules. The other two grammar rules are, in a sense, computational rules, because they combine a terminal symbol, to which an object can be associated, with a nonterminal, which can be expected to represent some construct. Presuming an evaluation that progresses upward in the parse tree, the nonterminal in the right side would already have its meaning attached. So, a syntax rule with a nonterminal as its RHS would require a function that computed the meaning of the LHS, which represents the meaning of the complete RHS.

The semantic function, named Mbin, maps the syntactic objects, as described in the previous grammar rules, to the objects in N, the set of non-negative decimal numbers. The function Mbin is defined as follows:

- Mbin `('0') = 0`
- Mbin `('1') = 1`
- Mbin `(<bin_num> '0') = 2 *` Mbin `(<bin_num>)`
- Mbin `(<bin_num>'1') = 2 *` Mbin `(<bin_num>) + 1`

The meanings, or denoted objects (which in this case are decimal numbers), can be attached to the nodes of the parse tree shown on the previous page, yielding the tree in Figure 3.10. This is syntax-directed semantics. Syntactic entities are mapped to mathematical objects with concrete meaning.

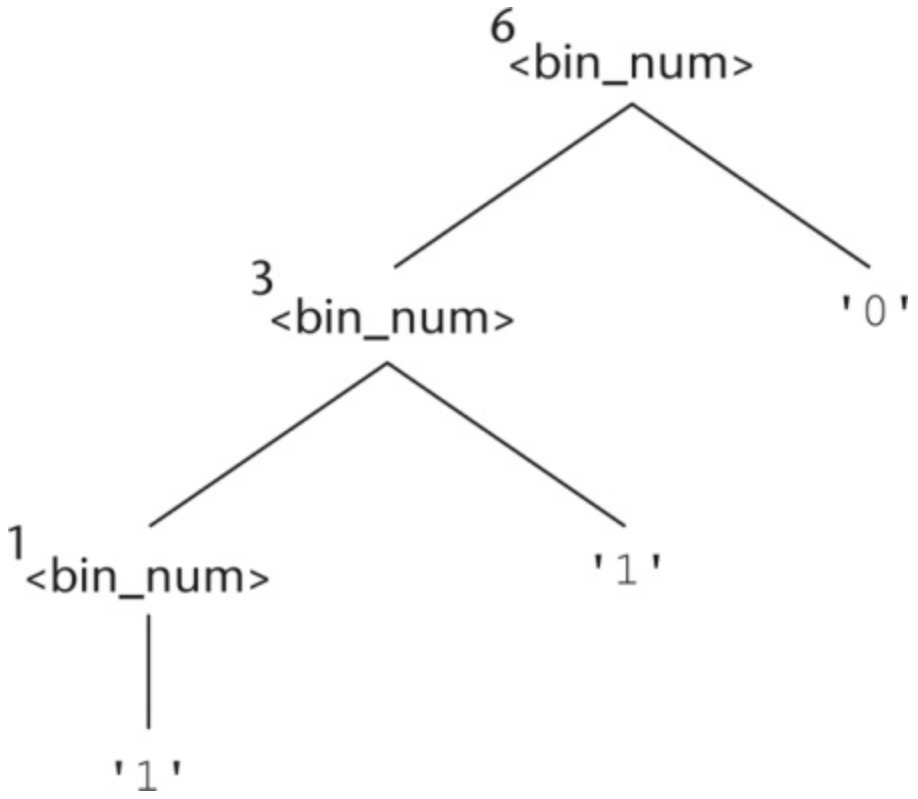

Figure 3.10 A parse tree with denoted objects for 110

Figure 3.10 Full Alternative Text

In part because we need it later, we now show a similar example for describing the meaning of syntactic decimal literals. In this case, the syntactic domain is the set of character string representations of decimal numbers. The semantic domain is once again the set N.

- <dec_num> → '0'|'1'|'2'|'3'|'4'|'5'|'6'|'7''8'|'9'
- |<dec_num> ('0'|'1'|'2'|'3'|'4'|'5'|'6'|'7'|'8'|'9')

The denotational mappings for these syntax rules are

- Mdec ('0') = 0, Mdec ('1') = 1, Mdec ('2') = 2, . . ., Mdec ('9') = 9

- Mdec (<dec_num> '0') = 10 * Mdec (<dec_num>)
- Mdec (<dec_num> '1') = 10 * Mdec (<dec_num>) +1
- . . .
- Mdec (<dec_num> '9') = 10 * Mdec (<dec_num>) +9

In the following sections, we present the denotational semantics descriptions of a few simple constructs. The most important simplifying assumption made here is that both the syntax and static semantics of the constructs are correct. In addition, we assume that only two scalar types are included: integer and Boolean.

3.5.2.2 The State of a Program

The denotational semantics of a program could be defined in terms of state changes in an ideal computer. Operational semantics are defined in this way, and denotational semantics are defined in nearly the same way. In a further simplification, however, denotational semantics is defined in terms of only the values of all of the program's variables. So, denotational semantics uses the state of the program to describe meaning, whereas operational semantics uses the state of a machine. The key difference between operational semantics and denotational semantics is that state changes in operational semantics are defined by coded algorithms, written in some programming language, whereas in denotational semantics, state changes are defined by mathematical functions.

Let the state s of a program be represented as a set of ordered pairs, as follows:

- s = { <i1, v1>, <i2, v2>, …, <in, vn>}

Each i is the name of a variable, and the associated v's are the current values of those variables. Any of the v's can have the special value **undef**, which indicates that its associated variable is currently undefined. Let VARMAP be a function of two parameters: a variable name and the program state. The

value of VARMAP (ij, s) is vj (the value paired with ij in state s). Most semantics mapping functions for programs and program constructs map states to states. These state changes are used to define the meanings of programs and program constructs. Some language constructs—for example, expressions—are mapped to values, not states.

3.5.2.3 Expressions

Expressions are fundamental to most programming languages. We assume here that expressions have no side effects. Furthermore, we deal with only very simple expressions: The only operators are + and *, and an expression can have at most one operator; the only operands are scalar integer variables and integer literals; there are no parentheses; and the value of an expression is an integer. Following is the BNF description of these expressions:

- <expr> → <dec_num> | <var> | <binary_expr>
- <binary_expr> → <left_expr> <operator> <right_expr>
- <left_expr> → <dec_num> | <var>
- <right_expr> → <dec_num> | <var>
- <operator> → + | *

The only error we consider in expressions is a variable having an undefined value. Obviously, other errors can occur, but most of them are machine--dependent. Let Z be the set of integers, and let **`error`** be the error value. Then $Z \cup$ {error} is the semantic domain for the denotational specification for our expressions.

The mapping function for a given expression E and state s follows. To distinguish between mathematical function definitions and the assignment statements of programming languages, we use the symbol Δ = to define mathematical functions. The implication symbol, =>, used in this definition connects the form of an operand with its associated case (or switch) construct. Dot notation is used to refer to the child nodes of a node. For

example, <binary_expr>.<left_expr> refers to the left child node of <binary_expr>.

- Me(<expr>, s) Δ= case <expr> of
- <dec_num>=> Mdec (<dec_num>, s)
- <var> =>if VARMAP (<var>, s) == **undef**
- then **error**
- else VARMAP(<var>, s)
- <binary_expr> =>
- if(Me (<binary_expr>.<left_expr>,s) == **undef** OR
- Me (<binary_expr>.<right_expr>, s) == **undef**)
- then **error**
- else if (<binary_expr>.<operator> == '+')
- then Me (<binary_expr>.<left_expr>, s) +
- Me (<binary_expr>.<right_expr>, s)
- else Me (<binary_expr>.<left_expr>, s) *
- Me (<binary_expr>.<right_expr>, s)

3.5.2.4 Assignment Statements

An assignment statement is an expression evaluation plus the setting of the target variable to the expression's value. In this case, the meaning function maps a state to a state. This function can be described with the following:

- Ma (x = E, s) Δ= if Me (E, s) == **error**
- then **error**
- else s' = {< i1, v1′ >, < i2, v2′>, . . . , < in, vn′>}, where
- for j = 1, 2, . . . , n
- if ij == x
- then vj′ = Me (E, s)
- else vj′ = VARMAP(ij,, s)

Note that the comparison in the third last line above, ij == x, is of names, not values.

3.5.2.5 Logical Pretest Loops

The denotational semantics of a logical pretest loop is deceptively simple. To expedite the discussion, we assume that there are two other existing mapping functions, Msl and Mb, that map statement lists and states to states and Boolean expressions to Boolean values (or **error**), respectively. The function is

- M1 (**while** B **do** L, s) Δ= if Mb (B, s) == **undef**
- then **error**
- else if Mb (B, s) == false
- then s

- else if Msl (L, s) == **error**
- then **error**
- else M1 (**while** B **do** L, Msl (L, s))

The meaning of the loop is simply the value of the program variables after the statements in the loop have been executed the prescribed number of times, assuming there have been no errors. In essence, the loop has been converted from iteration to recursion, where the recursion control is mathematically defined by other recursive state mapping functions. Recursion is easier to describe with mathematical rigor than iteration.

One significant observation at this point is that this definition, like actual program loops, may compute nothing because of nontermination.

3.5.2.6 Evaluation

Objects and functions, such as those used in the earlier constructs, can be defined for the other syntactic entities of programming languages. When a complete system has been defined for a given language, it can be used to determine the meaning of complete programs in that language. This provides a framework for thinking about programming in a highly rigorous way.

history note

A significant amount of work has been done on the possibility of using denotational language descriptions to generate compilers automatically (Jones, 1980; Milos et al., 1984; Bodwin et al., 1982). These efforts have shown that the method is feasible, but the work has never progressed to the point where it can be used to generate useful compilers.

As stated previously, denotational semantics can be used as an aid to language design. For example, statements for which the denotational

semantic description is complex and difficult may indicate to the designer that such statements may also be difficult for language users to understand and that an alternative design may be in order.

Because of the complexity of denotational descriptions, they are of little use to language users. On the other hand, they provide an excellent way to describe a language concisely.

Although the use of denotational semantics is normally attributed to Scott and Strachey (1971), the general denotational approach to language description can be traced to the nineteenth century (Frege, 1892).

3.5.3 Axiomatic Semantics

Axiomatic semantics, thus named because it is based on mathematical logic, is the most abstract approach to semantics specification discussed in this chapter. Rather than directly specifying the meaning of a program, axiomatic semantics specifies what can be proven about the program. Recall that one of the possible uses of semantic specifications is to prove the correctness of programs.

In axiomatic semantics, there is no model of the state of a machine or program or model of state changes that take place when the program is executed. The meaning of a program is based on relationships among program variables and constants, which are the same for every execution of the program.

Axiomatic semantics has two distinct applications: program verification and program semantics specification. This section focuses on program verification in its description of axiomatic semantics.

Axiomatic semantics was defined in conjunction with the development of an approach to proving the correctness of programs. Such correctness proofs, when they can be constructed, show that a program performs the computation described by its specification. In a proof, each statement of a program is both preceded and followed by a logical expression that specifies constraints on

program variables. These, rather than the entire state of an abstract machine (as with operational semantics), are used to specify the meaning of the statement. The notation used to describe constraints—indeed, the language of axiomatic semantics—is predicate calculus. Although simple Boolean expressions are often adequate to express constraints, in some cases they are not.

When axiomatic semantics is used to specify formally the meaning of a statement, the meaning is defined by the statement's effect on assertions about the data affected by the statement.

3.5.3.1 Assertions

The logical expressions used in axiomatic semantics are called predicates, or **assertions**. An assertion immediately preceding a program statement describes the constraints on the program variables at that point in the program. An assertion immediately following a statement describes the new constraints on those variables (and possibly others) after execution of the statement. These assertions are called the **precondition** and **postcondition**, respectively, of the statement. For two adjacent statements, the postcondition of the first serves as the precondition of the second. Developing an axiomatic description or proof of a given program requires that every statement in the program has both a precondition and a postcondition.

In the following sections, we examine assertions from the point of view that preconditions for statements are computed from given postconditions, although it is possible to consider these in the opposite sense. We assume all variables are integer type. As a simple example, consider the following assignment statement and postcondition:

```
sum = 2 * x + 1 {sum > 1}
```

Precondition and postcondition assertions are presented in braces to distinguish them from parts of program statements. One possible precondition for this statement is `{x > 10}`.

In axiomatic semantics, the meaning of a specific statement is defined by its

precondition and its postcondition. In effect, the two assertions specify precisely the effect of executing the statement.

In the following subsections, we focus on correctness proofs of statements and programs, which is a common use of axiomatic semantics. The more general concept of axiomatic semantics is to state precisely the meaning of statements and programs in terms of logic expressions. Program verification is one application of axiomatic descriptions of languages.

3.5.3.2 Weakest Preconditions

The **weakest precondition** is the least restrictive precondition that will guarantee the validity of the associated postcondition. For example, in the statement and postcondition given in Section 3.5.3.1, `{x > 10}`, `{x > 50}`, and `{x > 1000}` are all valid preconditions. The weakest of all preconditions in this case is `{x > 0}`.

If the weakest precondition can be computed from the most general postcondition for each of the statement types of a language, then the processes used to compute these preconditions provide a concise description of the semantics of that language. Furthermore, correctness proofs can be constructed for programs in that language. A program proof is begun by using the characteristics of the results of the program's execution as the postcondition of the last statement of the program. This postcondition, along with the last statement, is used to compute the weakest precondition for the last statement. This precondition is then used as the postcondition for the second last statement. This process continues until the beginning of the program is reached. At that point, the precondition of the first statement states the conditions under which the program will compute the desired results. If these conditions are implied by the input specification of the program, the program has been verified to be correct.

An **inference rule** is a method of inferring the truth of one assertion on the basis of the values of other assertions. The general form of an inference rule is as follows:

S1, S2, …, SnS

This rule states that if S1, S2, . . . , and S*n* are true, then the truth of S can be inferred. The top part of an inference rule is called its **antecedent**; the bottom part is called its **consequent**.

An **axiom** is a logical statement that is assumed to be true. Therefore, an axiom is an inference rule without an antecedent.

For some program statements, the computation of a weakest precondition from the statement and a postcondition is simple and can be specified by an axiom. In most cases, however, the weakest precondition can be specified only by an inference rule.

To use axiomatic semantics with a given programming language, whether for correctness proofs or for formal semantics specifications, either an axiom or an inference rule must exist for each kind of statement in the language. In the following subsections, we present an axiom for assignment statements and inference rules for statement sequences, selection statements, and logical pretest loop statements. Note that we assume that neither arithmetic nor - Boolean expressions have side effects.

3.5.3.3 Assignment Statements

The precondition and postcondition of an assignment statement together define its meaning. To define the meaning of an assignment statement there must be a way to compute its precondition from its postcondition.

Let x = E be a general assignment statement and Q be its postcondition. Then, its weakest precondition, P, is defined by the axiom

- $P = Q_{xSE}$

which means that P is computed as Q with all instances of x replaced by E. For example, if we have the assignment statement and postcondition

```
a = b / 2 - 1 {a < 10}
```

the weakest precondition is computed by substituting `b / 2 - 1` for `a` in the postcondition `{a < 10}`, as follows:

```
b / 2 - 1 < 10
b < 22
```

Thus, the weakest precondition for the given assignment statement and postcondition is `{b < 22}`. Remember that the assignment axiom is guaranteed to be correct only in the absence of side effects. An assignment statement has a side effect if it changes some variable other than its target.

The usual notation for specifying the axiomatic semantics of a given statement form is

{P} S {Q}

where P is the precondition, Q is the postcondition, and S is the statement form. In the case of the assignment statement, the notation is

- $\{Q_{x \to E}\}\ x = E \{Q\}$

As another example of computing a precondition for an assignment statement, consider the following:

```
x = 2 * y - 3 {x > 25}
```

The precondition is computed as follows:

```
2 * y - 3 > 25
y > 14
```

So `{y > 14}` is the weakest precondition for this assignment statement and postcondition.

Note that the appearance of the left side of the assignment statement in its right side does not affect the process of computing the weakest precondition. For example, for

```
x = x + y - 3 {x > 10}
```

the weakest precondition is

```
x + y - 3 > 10
y > 13 - x
```

Recall that axiomatic semantics was developed to prove the correctness of programs. In light of that, it is natural at this point to wonder how the axiom for assignment statements can be used to prove anything. Here is how: A given assignment statement with both a precondition and a postcondition can be considered a logical statement, or theorem. If the assignment axiom, when applied to the postcondition and the assignment statement, produces the given precondition, the theorem is proved. For example, consider the following logical statement:

```
{x > 3} x = x - 3 {x > 0}
```

Using the assignment axiom on the statement and its postcondition produces `{x > 3}`, which is the given precondition. Therefore, we have proven the example logical statement.

Next, consider the following logical statement:

```
{x > 5} x = x - 3 {x > 0}
```

In this case, the given precondition, `{x > 5}`, is not the same as the assertion produced by the axiom. However, it is obvious that `{x > 5}` implies `{x > 3}`. To use this in a proof, an inference rule named the **rule of consequence** is needed. The form of the rule of consequence is

{P} S {Q}, P′ => P, Q => Q′{P′} S{Q′}

The => symbol means “implies,” and S can be any program statement. The rule can be stated as follows: If the logical statement {P} S{Q} is true, the assertion P′ implies the assertion P, and the assertion Q implies the assertion Q′, then it can be inferred that {P′} S{Q′}. In other words, the rule of consequence says that a postcondition can always be weakened and a precondition can always be strengthened. This is quite useful in program proofs. For example, it allows the completion of the proof of the last logical statement example above. If we let P be `{x > 3}`, Q and Q′ be `{x > 0}`, and P

′ be {x > 5}, we have

{x > 3}x = x − 3{x > 0},(x > 5)=>{x > 3},(x > 0)=>(x > 0)
{x > 5}x = x − 3{x > 0}

The first term of the antecedent ({x > 3} x = x - 3 {x > 0}) was proven with the assignment axiom. The second and third terms are obvious. Therefore, by the rule of consequence, the consequent is true.

3.5.3.4 Sequences

The weakest precondition for a sequence of statements cannot be described by an axiom, because the precondition depends on the particular kinds of statements in the sequence. In this case, the precondition can only be described with an inference rule. Let S1 and S2 be adjacent program statements. If S1 and S2 have the following pre- and postconditions

{P1} S1 {P2} {P2} S2 {P3}

the inference rule for such a two-statement sequence is

{P1} S1 {P2}, {P2} S2 {P3}{P1} S1, S2 {P3}

So, for our example, {P1} S1; S2 {P3} describes the axiomatic semantics of the sequence S1; S2. The inference rule states that to get the sequence precondition, the precondition of the second statement is computed. This new assertion is then used as the postcondition of the first statement, which can then be used to compute the precondition of the first statement, which is also the precondition of the whole sequence. If S1 and S2 are the assignment statements

x1=E1

and

x2=E2

then we have

{P3x2→E2} x2=E2 {P3} {(P3x2→E2)x1→E1} x1=E1 {P3x2→E2}

Therefore, the weakest precondition for the sequence x1 = E1; x2 = E2 with postcondition P3 is {(P3x2→E2)x1→E1}.

For example, consider the following sequence and postcondition:

```
y = 3 * x + 1;
x = y + 3;
{x < 10}
```

The precondition for the second assignment statement is

```
y < 7
```

which is used as the postcondition for the first statement. The precondition for the first assignment statement can now be computed:

```
3 * x + 1 < 7
x < 2
```

So, `{x < 2}` is the precondition of both the first statement and the two--statement sequence.

3.5.3.5 Selection

We next consider the inference rule for selection statements, the general form of which is

- **`if`** B **`then`** S1 **`else`** S2

We consider only selections that include **`else`** clauses. The inference rule is

{B and P} S1 {Q}, {(not B) and P} S2 {Q}
{P} if B bb{then} S1 bb{else} S2 {Q}}

This rule specifies that selection statements must be proven both when the

Boolean control expression is true and when it is false. The first logical statement above the line represents the **`then`** clause; the second represents the **`else`** clause. According to the inference rule, we need a precondition P that can be used in the precondition of both the **`then`** and **`else`** clauses.

Consider the following example of the computation of the precondition using the selection inference rule. The example selection statement is

```
if x > 0 then
  y = y - 1
else
  y = y + 1
```

Suppose the postcondition, Q, for this selection statement is `{y > 0}`. We can use the axiom for assignment on the **`then`** clause

```
y = y - 1 {y > 0}
```

This produces `{y - 1 > 0}` or `{y > 1}`. It can be used as the P part of the precondition for the **`then`** clause. Now we apply the same axiom to the **`else`** clause

```
y = y + 1 {y > 0}
```

which produces the precondition `{y + 1 > 0}` or `{y > -1}`. Because `{y > 1}` => `{y > -1}`, the rule of consequence allows us to use `{y > 1}` for the precondition of the whole selection statement.

3.5.3.6 Logical Pretest Loops

Another essential construct of imperative programming languages is the logical pretest, or **`while`** loop. Computing the weakest precondition for a **`while`** loop is inherently more difficult than for a sequence, because the number of iterations cannot always be predetermined. In a case where the number of iterations is known, the loop can be unrolled and treated as a sequence.

The problem of computing the weakest precondition for loops is similar to

the problem of proving a theorem about all positive integers. In the latter case, induction is normally used, and the same inductive method can be used for some loops. The principal step in induction is finding an inductive hypothesis. The corresponding step in the axiomatic semantics of a **`while`** loop is finding an assertion called a **loop invariant**, which is crucial to finding the weakest precondition.

The inference rule for computing the precondition for a **`while`** loop is as follows:

{I and B} S {I}{I} while B do S end {I and (not B)}

In this rule, I is the loop invariant. This seems simple, but it is not. The complexity lies in finding an appropriate loop invariant.

The axiomatic description of a **`while`** loop is written as

- {P} **`while`** B **`do`** S **`end`** {Q}

The loop invariant must satisfy a number of requirements to be useful. First, the weakest precondition for the **`while`** loop must guarantee the truth of the loop invariant. In turn, the loop invariant must guarantee the truth of the postcondition upon loop termination. These constraints move us from the inference rule to the axiomatic description. During execution of the loop, the truth of the loop invariant must be unaffected by the evaluation of the loop-controlling Boolean expression and the loop body statements. Hence, the name *invariant*.

Another complicating factor for **`while`** loops is the question of loop termination. A loop that does not terminate cannot be correct, and in fact computes nothing. If Q is the postcondition that holds immediately after loop exit, then a precondition P for the loop is one that guarantees Q at loop exit and also guarantees that the loop terminates.

The complete axiomatic description of a **`while`** construct requires all of the following to be true, in which I is the loop invariant:

- P => I

- {I and B} S { I }
- (I and (not B)) => Q

the loop terminates

If a loop computes a sequence of numeric values, it may be possible to find a loop invariant using an approach that is used for determining the inductive hypothesis when mathematical induction is used to prove a statement about a mathematical sequence. The relationship between the number of iterations and the precondition for the loop body is computed for a few cases, with the hope that a pattern emerges that will apply to the general case. It is helpful to treat the process of producing a weakest precondition as a function, wp. In general

wp(statement, postcondition)=precondition

A wp function is often called a **predicate transformer**, because it takes a predicate, or assertion, as a parameter and returns another predicate.

To find I, the loop postcondition Q is used to compute preconditions for several different numbers of iterations of the loop body, starting with none. If the loop body contains a single assignment statement, the axiom for assignment statements can be used to compute these cases. Consider the example loop:

```
while y <> x do y = y + 1 end {y = x}
```

Remember that the equal sign is being used for two different purposes here. In assertions, it means mathematical equality; outside assertions, it means the assignment operator.

For zero iterations, the weakest precondition is, obviously,

```
{y = x}
```

For one iteration, it is

- `wp(y = y + 1, {y = x}) = {y + 1 = x}`, or `{y = x - 1}`

For two iterations, it is

- wp(y = y + 1, {y = x - 1})={y + 1 = x - 1}, or {y = x - 2}

For three iterations, it is

- wp(y = y + 1, {y = x - 2})={y + 1 = x - 2}, or {y = x – 3}

It is now obvious that {y < x} will suffice for cases of one or more iterations. Combining this with {y = x} for the zero iterations case, we get {y <= x}, which can be used for the loop invariant. A precondition for the **while** statement can be determined from the loop invariant. In fact, I can be used as the precondition, P.

We must ensure that our choice satisfies the four criteria for I for our example loop. First, because P = I, P => I. The second requirement is that the following must be true:

{ I and B } S { I }

In our example, we have

{y <= x and y <> x} y = y + 1 {y <= x}

Applying the assignment axiom to

y = y + 1 {y <= x}

we get {y + 1 <= x}, which is equivalent to {y < x}, which is implied by {y <= x and y <> x}. So, the earlier statement is proven.

Next, we must have

- {I and (not B)} => Q

In our example, we have

- {(y <= x) and not (y <> x)} => {y = x}
- {(y <= x) and (y = x)} => {y = x}

- `{y = x} => {y = x}`

So, this is obviously true. Next, loop termination must be considered. In this example, the question is whether the loop

```
{y <= x} while y <> x do y = y + 1 end {y = x}
```

terminates. Recalling that `x` and `y` are assumed to be integer variables, it is easy to see that this loop does terminate. The precondition guarantees that `y` initially is not larger than `x`. The loop body increments `y` with each iteration, until `y` is equal to `x`. No matter how much smaller `y` is than `x` initially, it will eventually become equal to `x`. So the loop will terminate. Because our choice of I satisfies all four criteria, it is a satisfactory loop invariant and loop precondition.

The previous process used to compute the invariant for a loop does not always produce an assertion that is the weakest precondition (although it does in the example).

As another example of finding a loop invariant using the approach used in mathematical induction, consider the following loop statement:

```
while  s > 1  do  s = s / 2  end  {s = 1}
```

As before, we use the assignment axiom to try to find a loop invariant and a precondition for the loop. For zero iterations, the weakest precondition is `{s = 1}`.

For one iteration, it is

- `wp(s = s / 2, {s = 1}) = {s / 2 = 1}`, or `{s = 2}`

For two iterations, it is

- `wp(s = s / 2, {s = 2}) = {s / 2 = 2}`, or `{s = 4}`

For three iterations, it is

- `wp(s = s / 2, {s = 4}) = {s / 2 = 4}`, or `{s = 8}`

From these cases, we can see clearly that the invariant is

- {s is a nonnegative power of 2}

Once again, the computed I can serve as P, and I passes the four requirements. Unlike our earlier example of finding a loop precondition, this one clearly is not a weakest precondition. Consider using the precondition {s > 1}. The logical statement

```
{s > 1} while  s > 1 do  s = s / 2 end {s = 1}
```

can easily be proven, and this precondition is significantly broader than the one computed earlier. The loop and precondition are satisfied for any positive value for s, not just powers of 2, as the process indicates. Because of the rule of consequence, using a precondition that is stronger than the weakest precondition does not invalidate a proof.

Finding loop invariants is not always easy. It is helpful to understand the nature of these invariants. First, a loop invariant is a weakened version of the loop postcondition and also a precondition for the loop. So, I must be weak enough to be satisfied prior to the beginning of loop execution, but when combined with the loop exit condition, it must be strong enough to force the truth of the postcondition.

Because of the difficulty of proving loop termination, that requirement is often ignored. If loop termination can be shown, the axiomatic description of the loop is called **total correctness**. If the other conditions can be met but termination is not guaranteed, it is called **partial correctness**.

In more complex loops, finding a suitable loop invariant, even for partial correctness, requires a good deal of ingenuity. Because computing the precondition for a **`while`** loop depends on finding a loop invariant, proving the correctness of programs with **`while`** loops using axiomatic semantics can be difficult.

3.5.3.7 Program Proofs

This section provides validations for two simple programs. The first example of a correctness proof is for a very short program, consisting of a sequence of three assignment statements that interchange the values of two variables.

```
{x = A AND y = B}
t = x;
x = y;
y = t;
{x = B AND y = A}
```

Because the program consists entirely of assignment statements in a sequence, the assignment axiom and the inference rule for sequences can be used to prove its correctness. The first step is to use the assignment axiom on the last statement and the postcondition for the whole program. This yields the precondition

```
{x = B AND t = A}
```

Next, we use this new precondition as a postcondition on the middle statement and compute its precondition, which is

```
{y = B AND t = A}
```

Next, we use this new assertion as the postcondition on the first statement and apply the assignment axiom, which yields

```
{y = B AND x = A}
```

which is the same as the precondition on the program, except for the order of operands on the `AND` operator. Because `AND` is a symmetric operator, our proof is complete.

The following example is a proof of correctness of a pseudocode program that computes the factorial function.

```
{n >= 0}
count = n;
fact = 1;
while count <> 0 do
    fact = fact * count;
    count = count - 1;
end
```

```
{fact = n!}
```

The method described earlier for finding the loop invariant does not work for the loop in this example. Some ingenuity is required here, which can be aided by a brief study of the code. The loop computes the factorial function in order of the last multiplication first; that is, `(n - 1) * n` is done first, assuming `n` is greater than `1`. So, part of the invariant can be the following:

```
fact = (count + 1) * (count + 2) * . . . * (n - 1) * n
```

But we also must ensure that `count` is always nonnegative, which we can do by adding that to the assertion above, to get the following:

```
I = (fact = (count + 1) * . . . * n) AND (count >= 0)
```

Next, we must confirm that this I meets the requirements for invariants. Once again we let I also be used for P, so P clearly implies I. The next question is

{ I and B } S { I }

I and B is the following:

```
((fact = (count + 1) * . . . * n) AND (count >= 0)) AND
    (count <> 0)
```

This reduces to

```
(fact = (count + 1) * . . . * n) AND (count > 0)
```

In our case, we must compute the precondition of the body of the loop, using the invariant for the postcondition. For

- {P} `count = count - 1 {I}`

we compute P to be

```
{(fact = count * (count + 1) * . . . * n) AND
    (count >= 1)}
```

Using this as the postcondition for the first assignment in the loop body,

- {P} `fact = fact * count {(fact = count * (count + 1)`
- `* . . . * n) AND (count >= 1)}`

In this case, P is

```
{(fact = (count + 1) * . . . * n) AND (count >= 1)}
```

It is clear that I and B implies this P, so by the rule of consequence,

- {I `AND` B} S {`I`}

is true. Finally, the last test of I is

- I `AND` (`NOT` B) => Q

For our example, this is

```
((fact = (count + 1) * . . . * n) AND (count >= 0)) AND
(count = 0)) => fact = n!
```

This is clearly true, for when `count = 0`, the first part is precisely the definition of factorial. So, our choice of I meets the requirements for a loop invariant. Now we can use our P (which is the same as I) from the **`while`** as the postcondition on the second assignment of the program

```
{P} fact = 1 {(fact = (count + 1) * . . . * n) AND
    (count >= 0)}
```

which yields for P

```
(1 = (count + 1) * . . . * n) AND (count >= 0))
```

Using this as the postcondition for the first assignment in the code

```
{P} count = n {(1 = (count + 1) * . . . * n) AND
    (count >= 0))}
```

produces for P

```
{(n + 1) * . . . * n = 1) AND (n >= 0)}
```

The left operand of the `AND` operator is true (because `1 = 1`) and the right operand is exactly the precondition of the whole code segment, `{n >= 0}`. Therefore, the program has been proven to be correct.

3.5.3.8 Evaluation

As stated previously, to define the semantics of a complete programming language using the axiomatic method, there must be an axiom or an inference rule for each statement type in the language. Defining axioms or inference rules for some of the statements of programming languages has proven to be a difficult task. An obvious solution to this problem is to design the language with the axiomatic method in mind, so that only statements for which axioms or inference rules can be written are included. Unfortunately, such a language would necessarily leave out some useful and powerful statements.

Axiomatic semantics is a powerful tool for research into program correctness proofs, and it provides an excellent framework in which to reason about programs, both during their construction and later. Its usefulness in describing the meaning of programming languages to language users and compiler writers is, however, highly limited.

SUMMARY

Backus-Naur Form and context-free grammars are equivalent metalanguages that are well suited for the task of describing the syntax of programming languages. Not only are they concise descriptive tools, but also the parse trees that can be associated with their generative actions give graphical evidence of the underlying syntactic structures. Furthermore, they are naturally related to recognition devices for the languages they generate, which leads to the relatively easy construction of syntax analyzers for compilers for these languages.

An attribute grammar is a descriptive formalism that can describe both the syntax and static semantics of a language. Attribute grammars are extensions to context-free grammars. An attribute grammar consists of a grammar, a set of attributes, a set of attribute computation functions, and a set of predicates that describe static semantics rules.

This chapter provides brief introductions to three methods of semantic description: operational, denotational, and axiomatic. Operational semantics is a method of describing the meaning of language constructs in terms of their effects on an ideal machine. In denotational semantics, mathematical objects are used to represent the meanings of language constructs. Language entities are converted to these mathematical objects with recursive functions. Axiomatic semantics, which is based on formal logic, was devised as a tool for proving the correctness of programs.

BIBLIOGRAPHIC NOTES

Syntax description using context-free grammars and BNF are thoroughly - discussed in Cleaveland and Uzgalis (1976).

Research in axiomatic semantics was begun by Floyd (1967) and further developed by Hoare (1969). The semantics of a large part of Pascal was described by Hoare and Wirth (1973) using this method. The parts they did not complete involved functional side effects and goto statements. These were found to be the most difficult to describe.

The technique of using preconditions and postconditions during the development of programs is described (and advocated) by Dijkstra (1976) and also discussed in detail in Gries (1981).

Good introductions to denotational semantics can be found in Gordon (1979) and Stoy (1977). Introductions to all of the semantics description methods discussed in this chapter can be found in Marcotty et al. (1976). Another good reference for much of the chapter material is Pagan (1981). The form of the denotational semantic functions in this chapter is similar to that found in Meyer (1990).

REVIEW QUESTIONS

1. Define *syntax* and *semantics*.
2. Who are language descriptions for?
3. Describe the operation of a general language generator.
4. Describe the operation of a general language recognizer.
5. What is the difference between a sentence and a sentential form?
6. Define a left-recursive grammar rule.
7. What three extensions are common to most EBNFs?
8. Distinguish between static and dynamic semantics.
9. What purpose do predicates serve in an attribute grammar?
10. What is the difference between a synthesized and an inherited attribute?
11. How is the order of evaluation of attributes determined for the trees of a given attribute grammar?
12. What is the primary use of attribute grammars?
13. Explain the primary uses of a methodology and notation for describing the semantics of programming languages.
14. Why can machine languages not be used to define statements in operational semantics?
15. Describe the two levels of uses of operational semantics.
16. In denotational semantics, what are the syntactic and semantic domains?

17. What is stored in the state of a program for denotational semantics?

18. Which semantics approach is most widely known?

19. What two things must be defined for each language entity in order to construct a denotational description of the language?

20. Which part of an inference rule is the antecedent?

21. What is a predicate transformer function?

22. What does partial correctness mean for a loop construct?

23. On what branch of mathematics is axiomatic semantics based?

24. On what branch of mathematics is denotational semantics based?

25. What is the problem with using a software pure interpreter for operational semantics?

26. Explain what the preconditions and postconditions of a given statement mean in axiomatic semantics.

27. Describe the approach of using axiomatic semantics to prove the correctness of a given program.

28. Describe the basic concept of denotational semantics.

29. In what fundamental way do operational semantics and denotational semantics differ?

PROBLEM SET

1. The two mathematical models of language description are generation and recognition. Describe how each can define the syntax of a programming language.

2. Write EBNF descriptions for the following:

    1. A Java class definition header statement

    2. A Java method call statement

    3. A C **`switch`** statement

    4. A C **`union`** definition

    5. C **`float`** literals

3. Rewrite the BNF of Example 3.4 to give `+` precedence over `*` and force `+` to be right associative.

4. Rewrite the BNF of Example 3.4 to add the `++` and `--` unary operators of Java.

5. Write a BNF description of the Boolean expressions of Java, including the three operators `&&`, `||`, and `!` and the relational expressions.

6. Using the grammar in Example 3.2, show a parse tree and a leftmost derivation for each of the following statements:

    1. `A = A * (B + (C * A))`

    2. `B = C * (A * C + B)`

    3. `A = A * (B + (C))`

7. Using the grammar in Example 3.4, show a parse tree and a leftmost derivation for each of the following statements:
    1. `A = (A + B) * C`
    2. `A = B + C + A`
    3. `A = A * (B + C)`
    4. `A = B * (C * (A + B))`
8. Prove that the following grammar is ambiguous:
    - <S> → <A>
    - <A> → <A> + <A> | <id>
    - <id> → a | b | c
9. Modify the grammar of Example 3.4 to add a unary minus operator that has higher precedence than either + or *.
10. Describe, in English, the language defined by the following grammar:
    - <S> → <A> <B> <C>
    - <A> → a <A> | a
    - <B> → b <B> | b
    - <C> → c <C> | c
11. Consider the following grammar:
    - <S> → <A> a <B> b
    - <A> → <A> b | b
    - <B> → a <B> | a

Which of the following sentences are in the language generated by this grammar?

1. baab
2. bbbab
3. bbaaaaas
4. bbaab

12. Consider the following grammar:

    - <S> → a <S> c <B> | <A> | b
    - <A> → c <A> | c
    - <B> → d | <A>

    Which of the following sentences are in the language generated by this grammar?

    1. abcd
    2. acccbd
    3. acccbcc
    4. acd
    5. accc

13. Write a grammar for the language consisting of strings that have *n* copies of the letter a followed by the same number of copies of the letter b, where $n > 0$. For example, the strings ab, aaaabbbb, and aaaaaaaabbbbbbbb are in the language but a, abb, ba, and aaabb are not.

14. Draw parse trees for the sentences aabb and aaaabbbb, as derived from the grammar of Problem 13.

15. Convert the BNF of Example 3.1 to EBNF.

16. Convert the BNF of Example 3.3 to EBNF.

17. Convert the following EBNF to BNF:

    - $S \rightarrow A\{bA\}$
    - $A \rightarrow a[b]A$

18. What is the difference between an intrinsic attribute and a nonintrinsic synthesized attribute?

19. Write an attribute grammar whose BNF basis is that of Example 3.6 in Section 3.4.5 but whose language rules are as follows: Data types cannot be mixed in expressions, but assignment statements need not have the same types on both sides of the assignment operator.

20. Write an attribute grammar whose base BNF is that of Example 3.2 and whose type rules are the same as for the assignment statement example of Section 3.4.5.

21. Using the virtual machine instructions given in Section 3.5.1.1, give an operational semantic definition of the following:

    1. Java **`do-while`**
    2. Ada **`for`**
    3. C++ **`if-then-else`**
    4. C **`for`**
    5. C **`switch`**

22. Write a denotational semantics mapping function for the following statements:

    1. Ada **`for`**

2. Java **`do-while`**
3. Java Boolean expressions
4. Java **`for`**
5. C **`switch`**

23. Compute the weakest precondition for each of the following assignment statements and postconditions:
    1. `a = 2 * (b - 1) - 1 {a > 0}`
    2. `b = (c + 10) / 3 {b > 6}`
    3. `a = a + 2 * b - 1 {a > 1}`
    4. `x = 2 * y + x - 1 {x > 11}`
24. Compute the weakest precondition for each of the following sequences of assignment statements and their postconditions:
    1. ```
       a = 2 * b + 1;
       b = a - 3
       {b < 0}
       ```
    2. ```
       a = 3 * (2 * b + a);
       b = 2 * a - 1
       {b > 5}
       ```
25. Compute the weakest precondition for each of the following selection constructs and their postconditions:
    1. ```
       if (a == b)
          b = 2 * a + 1
       ```
       ```

```
   else
    b = 2 * a;
   {b > 1}
```

2.
```
if (x < y)
  x = x + 1
else
  x = 3 * x
{x < 0}
```

3.
```
if (x > y)
   y = 2 * x + 1
else
   y = 3 * x - 1;
{y > 3}
```

26. Explain the four criteria for proving the correctness of a logical pretest loop construct of the form **`while`** B **`do`** S **`end`**.

27. Prove that (n+1) *…* n=1.

28. Prove the following program is correct:

```
{n > 0}
count = n;
sum = 0;
while  count <> 0  do
  sum = sum + count;
  count = count - 1;
end
{sum = 1 + 2 + . . . + n}
```

4 Lexical and Syntax Analysis

This chapter begins with an introduction to lexical analysis, along with a - simple example. Next, the general parsing problem is discussed, including the two primary approaches to parsing, and the complexity of parsing. Then, we - introduce the recursive-descent implementation technique for top-down parsers, including examples of parts of a recursive-descent parser and a trace of a parse using one. The last section discusses bottom-up parsing and the LR parsing algorithm. This section includes an example of a small LR parsing table and the parse of a string using the LR parsing process.

4.1 Introduction

A serious investigation of compiler design requires at least a semester of intensive study, including the design and implementation of a compiler for a small but realistic programming language. The first part of such a course is devoted to lexical and syntax analyses. The syntax analyzer is the heart of a compiler, because several other important components, including the semantic analyzer and the intermediate code generator, are driven by the actions of the syntax analyzer.

Some readers may wonder why a chapter on any part of a compiler would be included in a book on programming languages. There are at least two reasons to include a discussion of lexical and syntax analyses in this text: First, syntax analyzers are based directly on the grammars discussed in Chapter 3, so it is natural to discuss them as an application of grammars. Second, lexical and syntax analyzers are needed in numerous situations outside compiler design. Many applications, among them program listing formatters, programs that compute the complexity of programs, and programs that must analyze and react to the contents of a configuration file, all need to do lexical and syntax analyses. Therefore, lexical and syntax analyses are important topics for software developers, even if they never need to write a compiler. Furthermore, some computer science programs no longer require students to take a compiler design course, which leaves students with no instruction in lexical or syntax analysis. In those cases, this chapter can be covered in the programming language course. In degree programs that require a compiler design course, this chapter can be skipped.

Three different approaches to implementing programming languages are introduced in Chapter 1: compilation, pure interpretation, and hybrid implementation. The compilation approach uses a program called a compiler, which translates programs written in a high-level programming language into machine code. Compilation is typically used to implement programming languages that are used for large applications, often written in languages such as C++ and COBOL. Pure interpretation systems perform no translation; rather, programs are interpreted in their original form by a software

interpreter. Pure interpretation is usually used for smaller systems in which execution efficiency is not critical, such as scripts embedded in HTML documents, written in languages such as JavaScript. Hybrid implementation systems translate programs written in high-level languages into intermediate forms, which are interpreted. These systems are now more widely used than ever, thanks in large part to the popularity of scripting languages. Traditionally, hybrid systems have resulted in much slower program execution than compiler systems. However, in recent years the use of Just-in-Time (JIT) compilers has become widespread, particularly for Java programs and programs written for the Microsoft .NET system. A JIT compiler, which translates intermediate code to machine code, is used on methods at the time they are first called. In effect, a JIT compiler transforms a hybrid system to a delayed compiler system.

All three of the implementation approaches just discussed use both lexical and syntax analyzers.

Syntax analyzers, or parsers, are nearly always based on a formal description of the syntax of programs. The most commonly used syntax-description formalism is context-free grammars, or BNF, which is introduced in Chapter 3. Using BNF, as opposed to using some informal syntax description, has at least three compelling advantages. First, BNF descriptions of the syntax of programs are clear and concise, both for humans and for software systems that use them. Second, the BNF description can be used as the direct basis for the syntax analyzer. Third, implementations based on BNF are relatively easy to maintain because of their modularity.

Nearly all compilers separate the task of analyzing syntax into two distinct parts, lexical analysis and syntax analysis, although this terminology is confusing. The lexical analyzer deals with small-scale language constructs, such as names and numeric literals. The syntax analyzer deals with the large-scale constructs, such as expressions, statements, and program units. Section 4.2 introduces lexical analyzers. Sections 4.3, 4.4, and 4.5 discuss syntax analyzers.

There are three reasons why lexical analysis is separated from syntax analysis:

1. Simplicity—Techniques for lexical analysis are less complex than those required for syntax analysis, so the lexical-analysis process can be simpler if it is separate. Also, removing the low-level details of lexical analysis from the syntax analyzer makes the syntax analyzer both smaller and less complex.

2. Efficiency—Although it pays to optimize the lexical analyzer, because lexical analysis requires a significant portion of total compilation time, it is not fruitful to optimize the syntax analyzer. Separation facilitates this selective optimization.

3. Portability—Because the lexical analyzer reads input program files and often includes buffering of that input, it is somewhat platform dependent. However, the syntax analyzer can be platform independent. It is always good to isolate machine-dependent parts of any software system.

4.2 Lexical Analysis

A lexical analyzer is essentially a pattern matcher. A pattern matcher attempts to find a substring of a given string of characters that matches a given character pattern. Pattern matching is a traditional part of computing. One of the earliest uses of pattern matching was with text editors, such as the `ed` line editor, which was introduced in an early version of UNIX. Since then, pattern matching has found its way into some programming languages—for example, Perl and JavaScript. It is also available through the standard class libraries of Java, C++, and C#.

A lexical analyzer serves as the front end of a syntax analyzer. Technically, lexical analysis is a part of syntax analysis. A lexical analyzer performs syntax analysis at the lowest level of program structure. An input program appears to a compiler as a single string of characters. The lexical analyzer collects characters into logical groupings and assigns internal codes to the groupings according to their structure. In Chapter 3, these logical groupings are named **lexemes**, and the internal codes for categories of these groupings are named **tokens**. Lexemes are recognized by matching the input character string against character string patterns. Although tokens are usually represented as integer values, for the sake of readability of lexical and syntax analyzers, they are often referenced through named constants.

Consider the following example of an assignment statement:

```
result = oldsum - value / 100;
```

Following are the tokens and lexemes of this statement:

Token	*Lexeme*
IDENT	result
ASSIGN_OP	=
IDENT	oldsum
SUB_OP	-
IDENT	value
DIV_OP	/
INT_LIT	100
SEMICOLON	;

Lexical analyzers extract lexemes from a given input string and produce the corresponding tokens. In the early days of compilers, lexical analyzers often processed an entire source program file and produced a file of tokens and lexemes. Now, however, most lexical analyzers are subprograms that locate the next lexeme in the input, determine its associated token code, and return them to the caller, which is the syntax analyzer. So, each call to the lexical analyzer returns a single lexeme and its token. The only view of the input program seen by the syntax analyzer is the output of the lexical analyzer, one token at a time.

The lexical-analysis process includes skipping comments and white space outside lexemes, as they are not relevant to the meaning of the program. Also, the lexical analyzer inserts lexemes for user-defined names into the symbol table, which is used by later phases of the compiler. Finally, lexical analyzers detect syntactic errors in tokens, such as ill-formed floating-point literals, and report such errors to the user.

There are three approaches for building a lexical analyzer:

1. Write a formal description of the token patterns of the language using a

descriptive language related to regular expressions.1 These descriptions are used as input to a software tool that automatically generates a lexical analyzer. There are many such tools available for this. The oldest of these, named lex, is commonly included as part of UNIX systems.

1. These regular expressions are the basis for the pattern-matching facilities now part of many programming languages, either directly or through a class library.

2. Design a state transition diagram that describes the token patterns of the language and write a program that implements the diagram.

3. Design a state transition diagram that describes the token patterns of the language and hand-construct a table-driven implementation of the state diagram.

A state transition diagram, or just **state diagram**, is a directed graph. The nodes of a state diagram are labeled with state names. The arcs are labeled with the input characters that cause the transitions among the states. An arc may also include actions the lexical analyzer must perform when the transition is taken.

State diagrams of the form used for lexical analyzers are representations of a class of mathematical machines called **finite automata**. Finite automata can be designed to recognize members of a class of languages called **regular languages**. Regular grammars are generative devices for regular languages. The tokens of a programming language are a regular language, and a lexical analyzer is a finite automaton.

We now illustrate lexical-analyzer construction with a state diagram and the code that implements it. The state diagram could simply include states and transitions for each and every token pattern. However, that approach results in a very large and complex diagram, because every node in the state diagram would need a transition for every character in the character set of the language being analyzed. We therefore consider ways to simplify it.

Suppose we need a lexical analyzer that recognizes only arithmetic expressions, including variable names and integer literals as operands.

Assume that the variable names consist of strings of uppercase letters, lowercase letters, and digits but must begin with a letter. Names have no length limitation. The first thing to observe is that there are 52 different characters (any uppercase or lowercase letter) that can begin a name, which would require 52 transitions from the transition diagram's initial state. However, a lexical analyzer is interested only in determining that it is a name and is not concerned with which specific name it happens to be. Therefore, we define a character class named LETTER for all 52 letters and use a single transition on the first letter of any name.

Another opportunity for simplifying the transition diagram is with the integer literal tokens. There are 10 different characters that could begin an integer literal lexeme. This would require 10 transitions from the start state of the state diagram. Because specific digits are not a concern of the lexical analyzer, we can build a much more compact state diagram if we define a character class named DIGIT for digits and use a single transition on any character in this character class to a state that collects integer literals.

Because our names can include digits, the transition from the node following the first character of a name can use a single transition on LETTER or DIGIT to continue collecting the characters of a name.

Next, we define some utility subprograms for the common tasks inside the lexical analyzer. First, we need a subprogram, which we can name `getChar`, that has several duties. When called, `getChar` gets the next character of input from the input program and puts it in the global variable `nextChar`. `getChar` also must determine the character class of the input character and put it in the global variable `charClass`. The lexeme being built by the lexical analyzer, which could be implemented as a character string or an array, will be named `lexeme`.

We implement the process of putting the character in `nextChar` into the string array `lexeme` in a subprogram named `addChar`. This subprogram must be explicitly called because programs include some characters that need not be put in `lexeme`, for example the white-space characters between lexemes. In a more realistic lexical analyzer, comments also would not be placed in `lexeme`.

When the lexical analyzer is called, it is convenient if the next character of input is the first character of the next lexeme. Because of this, a function named `getNonBlank` is used to skip white space every time the analyzer is called.

Finally, a subprogram named `lookup` is needed to compute the token code for the single-character tokens. In our example, these are parentheses and the arithmetic operators. Token codes are numbers arbitrarily assigned to tokens by the compiler writer.

The state diagram in Figure 4.1 describes the patterns for our tokens. It includes the actions required on each transition of the state diagram.

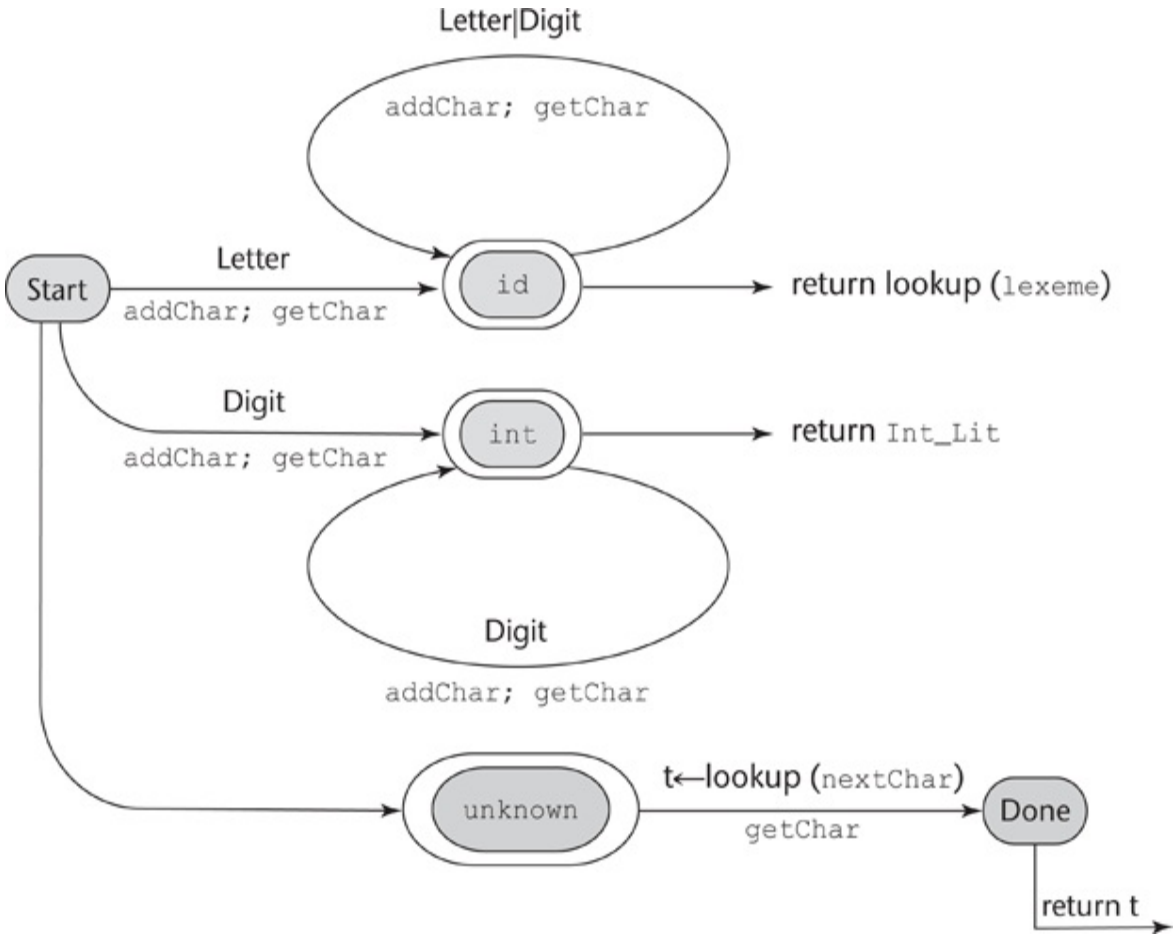

Figure 4.1 A state diagram to

recognize names, parentheses, and arithmetic operators

Figure 4.1 Full Alternative Text

The following is a C implementation of a lexical analyzer specified in the state diagram of Figure 4.1, including a main driver function for testing purposes:

```
/* front.c - a lexical analyzer system for simple
             arithmetic expressions */
#include <stdio.h>
#include <ctype.h>
/* Global declarations */
/* Variables */
int  charClass;
char  lexeme [100];
char  nextChar;
int  lexLen;
int  token;
int  nextToken;
FILE *in_fp, *fopen();
/* Function declarations */
void  addChar();
void  getChar();
void  getNonBlank();
int  lex();
/* Character classes */
#define LETTER 0
#define DIGIT 1
#define UNKNOWN 99
/* Token codes */
#define INT_LIT 10
#define IDENT 11
#define ASSIGN_OP 20
#define ADD_OP 21
#define SUB_OP 22
#define MULT_OP 23
#define DIV_OP 24
#define LEFT_PAREN 25
#define RIGHT_PAREN 26
/*****************************************************/
```

```
/* main driver */
main() {
/* Open the input data file and process its contents */
   if  ((in_fp = fopen("front.in", "r")) == NULL)
     printf("ERROR - cannot open front.in \n");
   else  {
     getChar();
     do   {
       lex();
    }  while  (nextToken! = EOF);
  }
}
/*****************************************************/
/* lookup - a function to lookup operators and parentheses
            and return the token */
int  lookup(char  ch) {
  switch  (ch) {
    case  '(':
      addChar();
      nextToken = LEFT_PAREN;
      break;
    case  ')':
      addChar();
      nextToken = RIGHT_PAREN;
      break;
    case  '+':
      addChar();
      nextToken = ADD_OP;
      break;
    case  '-':
      addChar();
      nextToken = SUB_OP;
      break;
    case  '*':
      addChar();
      nextToken = MULT_OP;
      break;
    case  '/':
      addChar();
      nextToken = DIV_OP;
      break;
    default:
      addChar();
      nextToken = EOF;
      break;
  }
  return  nextToken;
}
```

```
/*****************************************************/
/* addChar - a function to add nextChar to lexeme */
void  addChar() {
  if  (lexLen <= 98) {
    lexeme[lexLen++] = nextChar;
    lexeme[lexLen] = 0;
  }
  else
    printf("Error - lexeme is too long \n");
}
/*****************************************************/
/* getChar - a function to get the next character of
             input and determine its character class */
 void getChar() {
   if  ((nextChar = getc(in_fp)) = EOF) {
     if  (isalpha(nextChar))
      charClass = LETTER;
     else if  (isdigit(nextChar))
           charClass = DIGIT;
          else  charClass = UNKNOWN;
   }
   else
     charClass = EOF;
}
/*****************************************************/
/* getNonBlank - a function to call getChar until it
                 returns a non-whitespace character */
void getNonBlank() {
  while  (isspace(nextChar))
    getChar();
}
/
*****************************************************/
/* lex - a simple lexical analyzer for arithmetic
         expressions */
int  lex() {
  lexLen = 0;
  getNonBlank();
  switch  (charClass) {
/* Parse identifiers */
    case  LETTER:
      addChar();
      getChar();
      while  (charClass == LETTER || charClass == DIGIT) {
        addChar();
        getChar();
      }
```

```
    nextToken = IDENT;
    break;
/* Parse integer literals */
    case  DIGIT:
      addChar();
      getChar();
      while  (charClass == DIGIT) {
       addChar();
       getChar();
   }
   nextToken = INT_LIT;
   break;
/* Parentheses and operators */
    case  UNKNOWN:
      lookup(nextChar);
      getChar();
      break;
/* EOF */
    case  EOF:
      nextToken = EOF;
      lexeme[0] = 'E';
      lexeme[1] = 'O';
      lexeme[2] = 'F';
      lexeme[3] = 0;
      break;
 } /* End of switch */
 printf("Next token is: %d, Next lexeme is %s\n",
         nextToken, lexeme);
  return  nextToken;
} /* End of function lex */
```

This code illustrates the relative simplicity of lexical analyzers. Of course, we have left out input buffering, as well as some other important details. - Furthermore, we have dealt with a very small and simple input language.

Consider the following expression:

```
(sum + 47) / total
```

Following is the output of the lexical analyzer of `front.c` when used on this expression:

```
Next token is: 25 Next lexeme is (
Next token is: 11 Next lexeme is sum
Next token is: 21 Next lexeme is +
```

```
Next token is: 10 Next lexeme is 47
Next token is: 26 Next lexeme is )
Next token is: 24 Next lexeme is /
Next token is: 11 Next lexeme is total
Next token is: -1 Next lexeme is EOF
```

Names and reserved words in programs have similar patterns. Although it is possible to build a state diagram to recognize every specific reserved word of a programming language, that would result in a prohibitively large state diagram. It is much simpler and faster to have the lexical analyzer recognize names and reserved words with the same pattern and use a lookup in a table of reserved words to determine which names are reserved words. Using this approach considers reserved words to be exceptions in the names token category.

A lexical analyzer often is responsible for the initial construction of the symbol table, which acts as a database of names for the compiler. The entries in the symbol table store information about user-defined names, as well as the attributes of the names. For example, if the name is that of a variable, the variable’s type is one of its attributes that will be stored in the symbol table. Names are usually placed in the symbol table by the lexical analyzer. The attributes of a name are usually put in the symbol table by some part of the compiler that is subsequent to the actions of the lexical analyzer.

4.3 The Parsing Problem

The part of the process of analyzing syntax that is referred to as *syntax analysis* is often called **parsing**. We will use these two interchangeably.

This section discusses the general parsing problem and introduces the two main categories of parsing algorithms, top-down and bottom-up, as well as the complexity of the parsing process.

4.3.1 Introduction to Parsing

Parsers for programming languages construct parse trees for given programs. In some cases, the parse tree is only implicitly constructed, meaning that perhaps only a traversal of the tree is generated. But in all cases, the information required to build the parse tree is created during the parse. Both parse trees and derivations include all of the syntactic information needed by a language processor.

There are two distinct goals of syntax analysis: First, the syntax analyzer must check the input program to determine whether it is syntactically correct. When an error is found, the analyzer must produce a diagnostic message and recover. In this case, recovery means it must get back to a normal state and continue its analysis of the input program. This step is required so that the compiler finds as many errors as possible during a single analysis of the input program. If it is not done well, error recovery may create more errors, or at least more error messages. The second goal of syntax analysis is to produce a complete parse tree, or at least trace the structure of the complete parse tree, for syntactically correct input. The parse tree (or its trace) is used as the basis for translation.

Parsers are categorized according to the direction in which they build parse trees. The two broad classes of parsers are **top-down**, in which the tree is built from the root downward to the leaves, and **bottom-up**, in which the parse tree is built from the leaves upward to the root.

In this chapter, we use a small set of notational conventions for grammar symbols and strings to make the discussion less cluttered. For formal languages, they are as follows:

1. Terminal symbols—lowercase letters at the beginning of the alphabet (a, b, . . .)

2. Nonterminal symbols—uppercase letters at the beginning of the alphabet (A, B, . . .)

3. Terminals or nonterminals—uppercase letters at the end of the alphabet (W, X, Y, Z)

4. Strings of terminals—lowercase letters at the end of the alphabet (w, x, y, z)

5. Mixed strings (terminals and/or nonterminals)—lowercase Greek letters (α, β, δ, γ)

For programming languages, terminal symbols are the small-scale syntactic constructs of the language, what we have referred to as lexemes. The nonterminal symbols of programming languages are usually connotative names or abbreviations, surrounded by angle brackets—for example, <while_statement>, <expr>, and <function_def>. The sentences of a language (programs, in the case of a programming language) are strings of terminals. Mixed strings describe right-hand sides (RHSs) of grammar rules and are used in parsing algorithms.

4.3.2 Top-Down Parsers

A top-down parser traces or builds a parse tree in preorder. A preorder traversal of a parse tree begins with the root. Each node is visited before its branches are followed. Branches from a particular node are followed in left-to-right order. This corresponds to a leftmost derivation.

In terms of the derivation, a top-down parser can be described as follows: Given a sentential form that is part of a leftmost derivation, the parser’s task

is to find the next sentential form in that leftmost derivation. The general form of a left sentential form is xAα, whereby our notational conventions x is a string of terminal symbols, A is a nonterminal, and α is a mixed string. Because x contains only terminals, A is the leftmost nonterminal in the sentential form, so it is the one that must be expanded to get the next sentential form in a leftmost derivation. Determining the next sentential form is a matter of choosing the correct grammar rule that has A as its LHS. For example, if the current sentential form is xAα and the A-rules are $A \rightarrow bB$, $A \rightarrow cBb$, and $A \rightarrow a$, a top-down parser must choose among these three rules to get the next sentential form, which could be xbBα, xcBbα, or xaα. This is the parsing decision problem for top-down parsers.

Different top-down parsing algorithms use different information to make parsing decisions. The most common top-down parsers choose the correct RHS for the leftmost nonterminal in the current sentential form by comparing the next token of input with the first symbols that can be generated by the RHSs of those rules. Whichever RHS has that token at the left end of the string it generates is the correct one. So, in the sentential form xAα, the parser would use whatever token would be the first generated by A to determine which A-rule should be used to get the next sentential form. In the example above, the three RHSs of the A-rules all begin with different terminal symbols. The parser can easily choose the correct RHS based on the next token of input, which must be a, b, or c in this example. In general, choosing the correct RHS is not so straightforward, because some of the RHSs of the leftmost nonterminal in the current sentential form may begin with a nonterminal.

The most common top-down parsing algorithms are closely related. A **recursive-descent parser** is a coded version of a syntax analyzer based directly on the BNF description of the syntax of language. The most common alternative to recursive descent is to use a parsing table, rather than code, to implement the BNF rules. Both of these, which are called **LL algorithms**, are equally powerful, meaning they work on the same subset of all context-free grammars. The first L in LL specifies a left-to-right scan of the input; the second L specifies that a leftmost derivation is generated. Section 4.4 introduces the recursive-descent approach to implementing an LL parser.

4.3.3 Bottom-Up Parsers

A bottom-up parser constructs a parse tree by beginning at the leaves and progressing toward the root. This parse order corresponds to the reverse of a rightmost derivation. That is, the sentential forms of the derivation are produced in order of last to first. In terms of the derivation, a bottom-up parser can be described as follows: Given a right sentential form α, the parser must determine what substring of α is the RHS of the rule in the grammar that must be reduced to its LHS to produce the previous sentential form in the rightmost derivation. For example, the first step for a bottom-up parser is to determine which substring of the initial given sentence is the RHS to be reduced to its corresponding LHS to get the second last sentential form in the derivation. The process of finding the correct RHS to reduce is complicated by the fact that a given right sentential form may include more than one RHS from the grammar of the language being parsed. The correct RHS is called the **handle**. A right sentential form is a sentential form that appears in a rightmost derivation.

Consider the following grammar and derivation:

- S → aAc
- A → aA | b
- S => aAc => aaAc => aabc

A bottom-up parser of this sentence, aabc, starts with the sentence and must find the handle in it. In this example, this is an easy task, for the string contains only one RHS, b. When the parser replaces b with its LHS, A, it gets the second to last sentential form in the derivation, aaAc. In the general case, as stated previously, finding the handle is much more difficult, because a sentential form may include several different RHSs.

A bottom-up parser finds the handle of a given right sentential form by examining the symbols on one or both sides of a possible handle. Symbols to the right of the possible handle are usually tokens in the input that have not yet been analyzed.

The most common bottom-up parsing algorithms are in the LR family, where the L specifies a left-to-right scan of the input and the R specifies that a rightmost derivation is generated.

4.3.4 The Complexity of Parsing

Parsing algorithms that work for any unambiguous grammar are complicated and inefficient. In fact, the complexity of such algorithms is O(n3), which means the amount of time they take is on the order of the cube of the length of the string to be parsed. This relatively large amount of time is required because these algorithms frequently must back up and reparse part of the sentence being analyzed. Reparsing is required when the parser has made a mistake in the parsing process. Backing up the parser also requires that part of the parse tree being constructed (or its trace) must be dismantled and rebuilt. O(n3) algorithms are normally not useful for practical processes, such as syntax analysis for a compiler, because they are far too slow. In situations such as this, computer scientists often search for algorithms that are faster, though less general. Generality is traded for efficiency. In terms of parsing, faster algorithms have been found that work for only a subset of the set of all possible grammars. These algorithms are acceptable as long as the subset includes grammars that describe programming languages. (Actually, as discussed in Chapter 3, the whole class of context-free grammars is not adequate to describe all of the syntax of most programming languages.)

All algorithms used for the syntax analyzers of commercial compilers have complexity O(n), which means the time they take is linearly related to the length of the string to be parsed. This is vastly more efficient than O(n3) algorithms.

4.4 Recursive-Descent Parsing

This section introduces the recursive-descent top-down parser implementation process.

4.4.1 The Recursive-Descent Parsing Process

A recursive-descent parser is so named because it consists of a collection of subprograms, many of which are recursive, and it produces a parse tree in top-down order. This recursion is a reflection of the nature of programming languages, which include several different kinds of nested structures. For example, statements are often nested in other statements. Also, parentheses in expressions must be properly nested. The syntax of these structures is naturally described with recursive grammar rules.

EBNF is ideally suited for recursive-descent parsers. Recall from Chapter 3 that the primary EBNF extensions are braces, which specify that what they enclose can appear zero or more times, and brackets, which specify that what they enclose can appear once or not at all. Note that in both cases, the enclosed symbols are optional. Consider the following examples:

- <if_statement> → **`if`** <logic_expr> <statement> [**`else`** <statement>]
- <ident_list> → ident {, ident}

In the first rule, the **`else`** clause of an **`if`** statement is optional. In the second, an <ident_list> is an identifier, followed by zero or more repetitions of a comma and an identifier.

A recursive-descent parser has a subprogram for each nonterminal in its associated grammar. The responsibility of the subprogram associated with a particular nonterminal is as follows: When given an input string, it traces out

the parse tree that can be rooted at that nonterminal and whose leaves match the input string. In effect, a recursive-descent parsing subprogram is a parser for the language (set of strings) that is generated by its associated nonterminal.

Consider the following EBNF description of simple arithmetic expressions:

- <expr> → <term> {(+ | -) <term>}
- <term> → <factor> {(* | /) <factor>}
- <factor> → id | int_constant | (<expr>)

Recall from Chapter 3 that an EBNF grammar for arithmetic expressions, such as this one, does not force any associativity rule. Therefore, when using such a grammar as the basis for a compiler, one must take care to ensure that the code generation process, which is normally driven by syntax analysis, produces code that adheres to the associativity rules of the language. This can be done easily when recursive-descent parsing is used.

In the following recursive-descent function, `expr`, the lexical analyzer is the function that is implemented in Section 4.2. It gets the next lexeme and puts its token code in the global variable `nextToken`. The token codes are defined as named constants, as in Section 4.2.

A recursive-descent subprogram for a rule with a single RHS is relatively simple. For each terminal symbol in the RHS, that terminal symbol is compared with `nextToken`. If they do not match, it is a syntax error. If they match, the lexical analyzer is called to get the next input token. For each nonterminal, the parsing subprogram for that nonterminal is called.

The recursive-descent subprogram for the first rule in the previous example grammar, written in C, is

```
/* expr
   Parses strings in the language generated by the rule:
   <expr> -> <term> {(+ | -) <term>}
   */
void  expr() {
  printf("Enter <expr>\n");
```

```
/* Parse the first term */
  term();
/* As long as the next token is + or -, get
   the next token and parse the next term */
  while  (nextToken == ADD_OP || nextToken == SUB_OP) {
    lex();
    term();
  }
  printf("Exit <expr>\n");
}  /* End of function expr */
```

Notice that the `expr` function includes tracing output statements, which are included to produce the example output shown later in this section.

Recursive-descent parsing subprograms are written with the convention that each one leaves the next token of input in `nextToken`. So, whenever a parsing function begins, it assumes that `nextToken` has the code for the leftmost token of the input that has not yet been used in the parsing process.

The part of the language that the `expr` function parses consists of one or more terms, separated by either plus or minus operators. This is the language generated by the nonterminal <expr>. Therefore, first it calls the function that parses terms (`term`). Then it continues to call that function as long as it finds `ADD_OP` or `SUB_OP` tokens (which it passes over by calling `lex`). This recursive-descent function is simpler than most, because its associated rule has only one RHS. Furthermore, it does not include any code for syntax error detection or recovery, because there are no detectable errors associated with the grammar rule.

A recursive-descent parsing subprogram for a nonterminal whose rule has more than one RHS begins with code to determine which RHS is to be parsed. Each RHS is examined (at compiler construction time) to determine the set of terminal symbols that can appear at the beginning of sentences it can generate. By matching these sets against the next token of input, the parser can choose the correct RHS.

The parsing subprogram for <term> is similar to that for <expr>:

```
/* term
   Parses strings in the language generated by the rule:
   <term> -> <factor> {(* | /) <factor>)
```

```
   */
void  term() {
  printf("Enter <term>\n");
/* Parse the first factor */
  factor();
/* As long as the next token is * or /, get the
   next token and parse the next factor */
  while  (nextToken == MULT_OP || nextToken == DIV_OP) {
    lex();
    factor();
  }
  printf("Exit <term>\n");
}  /* End of function term */
```

The function for the <factor> nonterminal of our arithmetic expression grammar must choose between its two RHSs. It also includes error detection. In the function for <factor>, the reaction to detecting a syntax error is simply to call the `error` function. In a real parser, a diagnostic message must be produced when an error is detected. Furthermore, parsers must recover from the error so that the parsing process can continue.

```
/* factor
   Parses strings in the language generated by the rule:
   <factor> -> id | int_constant | ( <expr )
   */
void factor() {
  printf("Enter <factor>\n");
/* Determine which RHS */
  if (nextToken == IDENT || nextToken == INT_LIT)
/* Get the next token */
    lex();
/* If the RHS is ( <expr> ), call lex to pass over the
   left parenthesis, call expr, and check for the right
   parenthesis */
  else  {
    if  (nextToken == LEFT_PAREN) {
      lex();
      expr();
      if (nextToken == RIGHT_PAREN)
        lex();
      else
        error();
    }  /* End of if (nextToken == ... */
/* It was not an id, an integer literal, or a left
   parenthesis */
    else error();
```

```
  } /* End of else */
  printf("Exit <factor>\n");;
} /* End of function factor */
```

Following is the trace of the parse of the example expression `(sum + 47) / total`, using the parsing functions `expr`, `term`, and `factor`, and the function `lex` from Section 4.2. Note that the parse begins by calling `lex` and the start symbol routine, in this case, `expr`.

```
Next token is: 25 Next lexeme is (
Enter <expr>
Enter <term>
Enter <factor>
Next token is: 11 Next lexeme is sum
Enter <expr>
Enter <term>
Enter <factor>
Next token is: 21 Next lexeme is +
Exit <factor>
Exit <term>
Next token is: 10 Next lexeme is 47
Enter <term>
Enter <factor>
Next token is: 26 Next lexeme is )
Exit <factor>
Exit <term>
Exit <expr>
Next token is: 24 Next lexeme is /
Exit <factor>
Next token is: 11 Next lexeme is total
Enter <factor>
Next token is: -1 Next lexeme is EOF
Exit <factor>
Exit <term>
Exit <expr>
```

The parse tree traced by the parser for the preceding expression is shown in Figure 4.2.

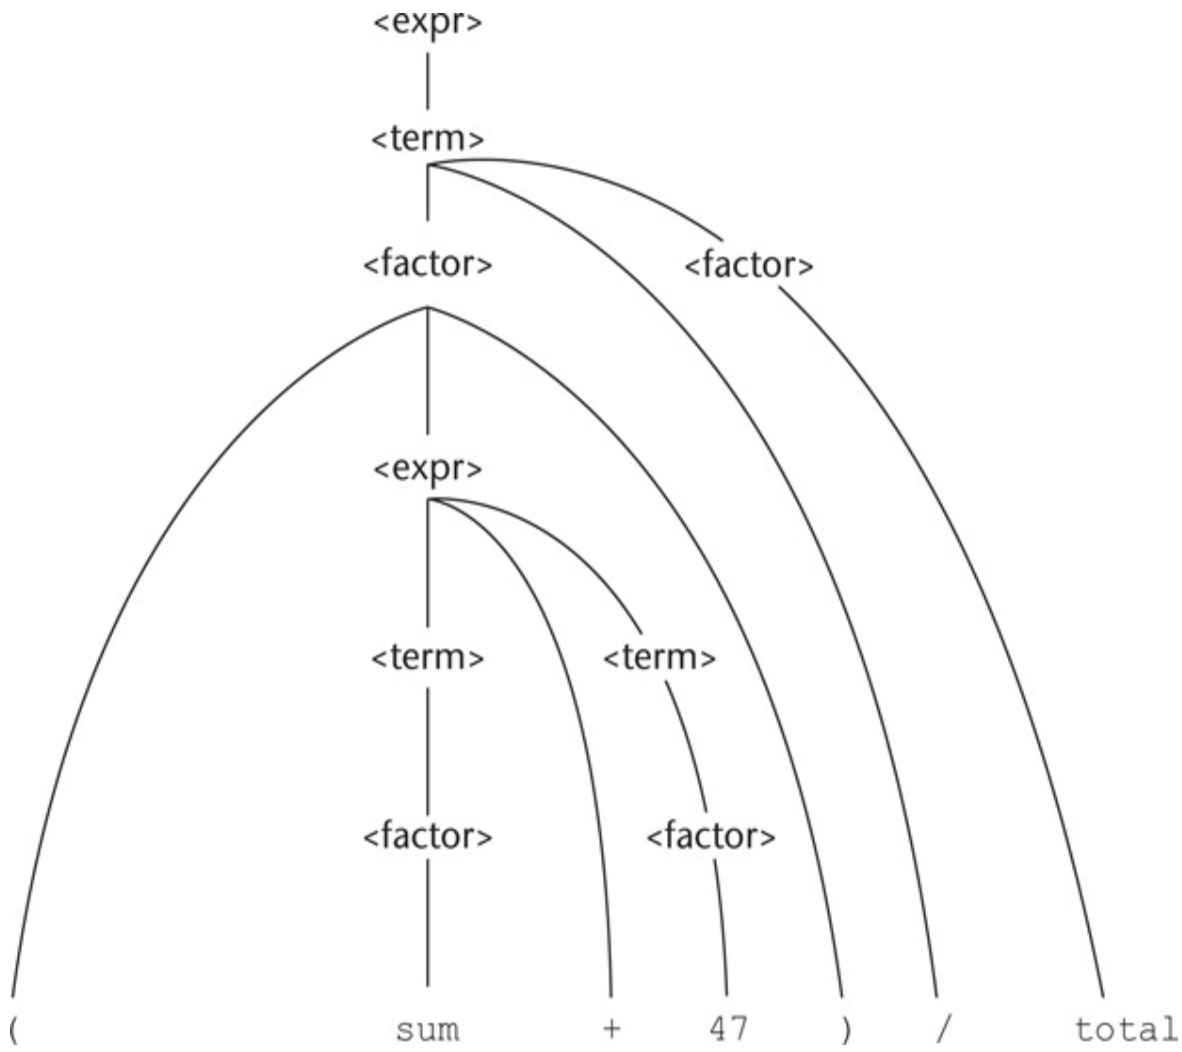

Figure 4.2 Parse tree for (sum + 47)/ total

Figure 4.2 Full Alternative Text

One more example grammar rule and parsing function should help solidify the reader's understanding of recursive-descent parsing. Following is a grammatical description of the Java **`if`** statement:

<ifstmt> → **`if`** (<boolexpr>) <statement> [**`else`** <statement>]

The recursive-descent subprogram for this rule follows:

```
/* Function ifstmt
    Parses strings in the language generated by the rule:
    <ifstmt> -> if (<boolexpr>)  <statement>
                [else <statement>]
    */
void  ifstmt() {
/* Be sure the first token is 'if' */
  if  (nextToken = IF_CODE)
    error();
  else  {
/* Call lex to get to the next token */
    lex();
/* Check for the left parenthesis */
     if  (nextToken = LEFT_PAREN)
       error();
     else  {
/* Parse the Boolean expression */
      boolexpr();
/* Check for the right parenthesis */
     if (nextToken = RIGHT_PAREN)
       error();
     else  {
/* Parse the then clause */
        statement();
/* If an else is next, parse the else clause */
        if  (nextToken == ELSE_CODE) {
/* Call lex to get over the else */
         lex();
         statement();
       } /* end of if (nextToken == ELSE_CODE ... */
     } /* end of else of if (nextToken != RIGHT ... */
    } /* end of else of if (nextToken != LEFT ... */
  } /* end of else of if (nextToken != IF_CODE ... */
} /* end of ifstmt */
```

Notice that this function uses parser functions for statements and Boolean expressions that are not given in this section.

The objective of these examples is to convince you that a recursive-descent parser can be easily written if an appropriate grammar is available for the language. The characteristics of a grammar that allows a recursive-descent parser to be built are discussed in the following subsection.

4.4.2 The LL Grammar Class

Before choosing to use recursive descent as a parsing strategy for a compiler or other program analysis tool, one must consider the limitations of the approach, in terms of grammar restrictions. This section discusses these restrictions and their possible solutions.

One simple grammar characteristic that causes a catastrophic problem for LL parsers is left recursion. For example, consider the following rule:

- $A \rightarrow A+B$

A recursive-descent parser subprogram for A immediately calls itself to parse the first symbol in its RHS. That activation of the A parser subprogram then immediately calls itself again, and again, and so forth. It is easy to see that this leads nowhere (except to stack overflow).

The left recursion in the rule $A \rightarrow A+B$ is called **direct left recursion**, because it occurs in one rule. Direct left recursion can be eliminated from a grammar by the following process:

For each nonterminal, A,

1. Group the A-rules as $A \rightarrow A\alpha 1, | \cdots | A\alpha m | \beta 1 | \beta 2 | \cdots | \beta n$ where none of the β's begins with A

2. Replace the original A-rules with

   $A \rightarrow \beta 1A' | \beta 2A' | \cdots | \beta nA'$ $A' \rightarrow \alpha 1A' | \alpha 2A' | \alpha mA' | \varepsilon$

Note that ε specifies the empty string. A rule that has ε as its RHS is called an *erasure rule*, because its use in a derivation effectively erases its LHS from the sentential form.

Consider the following example grammar and the application of the above process:

$E \rightarrow E+T \mid T \; T \rightarrow T * F \mid F \; F \rightarrow (E)+id$

For the E-rules, we have $\alpha 1 = \; + T$ and $\beta = T$, so we replace the E-rules with

$E \rightarrow T \; E' \; E' \rightarrow +T \; E' \mid \varepsilon$

For the T-rules, we have $\alpha 1 = *F$ and $\beta = F$, so we replace the T-rules with

$T \rightarrow F \; T' \; T \; ' \rightarrow *F \; T' \mid \varepsilon$

Because there is no left recursion in the F-rules, they remain the same, so the complete replacement grammar is

$E \rightarrow T \; E' \; E' \rightarrow +T \; E' \mid \varepsilon \; T \rightarrow F \; T' \; T' \rightarrow \; * \; F \; T' \mid \varepsilon \; F \rightarrow (E) \mid id$

This grammar generates the same language as the original grammar but is not left recursive.

As was the case with the expression grammar written using EBNF in Section 4.4.1, this grammar does not specify left associativity of operators. However, it is relatively easy to design the code generation based on this grammar so that the addition and multiplication operators will have left associativity.

Indirect left recursion poses the same problem as direct left recursion. For example, suppose we have

$A \; \rightarrow \; B \; a \; A \; B \; \rightarrow \; A \; b$

A recursive-descent parser for these rules would have the A subprogram immediately call the subprogram for B, which immediately calls the A subprogram. So, the problem is the same as for direct left recursion. The problem of left recursion is not confined to the recursive-descent approach to building top-down parsers. It is a problem for all top-down parsing algorithms. Fortunately, left recursion is not a problem for bottom-up parsing algorithms.

There is an algorithm to modify a given grammar to remove indirect left recursion (Aho et al., 2006), but it is not covered here. When writing a - grammar for a programming language, one can usually avoid including left

recursion, both direct and indirect.

Left recursion is not the only grammar trait that disallows top-down parsing. Another is whether the parser can always choose the correct RHS on the basis of the next token of input, using only the first token generated by the leftmost nonterminal in the current sentential form. There is a relatively simple test of a non-left recursive grammar that indicates whether this can be done, called the **pairwise disjointness test**. This test requires the ability to compute a set based on the RHSs of a given nonterminal symbol in a grammar. These sets, which are called FIRST, are defined as

- FIRST (α) = {a | α =>* aβ} (IF α =>* ε, ε is in FIRST (α))

in which =>* means 0 or more derivation steps.

An algorithm to compute FIRST for any mixed string α can be found in Aho et al. (2006). For our purposes, FIRST can usually be computed by inspection of the grammar.

The pairwise disjointness test is as follows:

For each nonterminal, A, in the grammar that has more than one RHS, for each pair of rules, $A \rightarrow \alpha i$ and $A \rightarrow \alpha j$, it must be true that

$FIRST(\alpha i) \cap FIRST(\alpha j) = \phi$

(The intersection of the two sets, FIRST(αi) and FIRST(αj), must be empty.)

In other words, if a nonterminal A has more than one RHS, the first terminal symbol that can be generated in a derivation for each of them must be unique to that RHS. Consider the following rules:

$A \rightarrow aB \mid bAb \mid Bb$ $B \rightarrow cB \mid d$

The FIRST sets for the RHSs of the A-rules are {a}, {b}, and {c}, {d}, which are clearly disjoint. Therefore, these rules pass the pairwise disjointness test. What this means, in terms of a recursive-descent parser, is that the code of the subprogram for parsing the nonterminal A can choose which RHS it is dealing with by seeing only the first terminal symbol of input (token) that is

generated by the nonterminal. Now consider the rules

A → aB | BAb B → aA | b

The FIRST sets for the RHSs in the A-rules are {a} and {a}, {b} which are clearly not disjoint. So, these rules fail the pairwise disjointness test. In terms of the parser, the subprogram for A could not determine which RHS was being parsed by looking at the next symbol of input, because if it were an a, it could be either RHS. This issue is of course more complex if one or more of the RHSs begin with nonterminals.

In many cases, a grammar that fails the pairwise disjointness test can be modified so that it will pass the test. For example, consider the rule

<variable> → identifier | identifier [<expression>]

This states that a <variable> is either an identifier or an identifier followed by an expression in brackets (a subscript). These rules clearly do not pass the pairwise disjointness test, because both RHSs begin with the same terminal, identifier. This problem can be alleviated through a process called **left factoring**.

We now take an informal look at left factoring. Consider our rules for <variable>. Both RHSs begin with identifier. The parts that follow identifier in the two RHSs are ε (the empty string) and [<expression>]. The two rules can be replaced by the following two rules:

<variable> → identifier <new>

<new> → ε | [<expression>]

It is not difficult to see that together, these two rules generate the same language as the two rules with which we began. However, these two pass the pairwise disjointness test.

If the grammar is being used as the basis for a recursive-descent parser, an alternative to left factoring is available. With an EBNF extension, the problem disappears in a way that is very similar to the left factoring solution.

Consider the original rules above for <variable>. The subscript can be made optional by placing it in square brackets, as in

<variable> → identifier [[<expression>]]

In this rule, the outer brackets are metasymbols that indicate that what is inside is optional. The inner brackets are terminal symbols of the programming language being described. The point is that we replaced two rules with a single rule that generates the same language but passes the pairwise disjointness test.

A formal algorithm for left factoring can be found in Aho et al. (2006). Left factoring cannot solve all pairwise disjointness problems of grammars. In some cases, rules must be rewritten in other ways to eliminate the problem.

4.5 Bottom-Up Parsing

This section introduces the general process of bottom-up parsing and includes a description of the LR parsing algorithm.

4.5.1 The Parsing Problem for Bottom-Up Parsers

Consider the following grammar for arithmetic expressions:

- E → E + T | T
- T → T * F | F
- F → (E) | id

Notice that this grammar generates the same arithmetic expressions as the example in Section 4.4. The difference is that this grammar is left recursive, which is acceptable to bottom-up parsers. Also note that grammars for bottom-up parsers normally do not include metasymbols such as those used to specify extensions to BNF. The following rightmost derivation illustrates this grammar:

- E => E+T
- => E + T * F
- => E + T * id
- => E + F * id
- => E + id * id

- => T + id * id
- => F + id * id
- => id + id * id

The underlined part of each sentential form in this derivation is the RHS that is rewritten as its corresponding LHS to get the previous sentential form. The process of bottom-up parsing produces the reverse of a rightmost derivation. So, in the example derivation, a bottom-up parser starts with the last sentential form (the input sentence) and produces the sequence of sentential forms from there until all that remains is the start symbol, which in this grammar is E. In each step, the task of the bottom-up parser is to find the specific RHS, the handle, in the sentential form that must be rewritten to get the next (previous) sentential form. As mentioned earlier, a right sentential form may include more than one RHS. For example, the right sentential form

- E + T * id

includes three RHSs, E+T, T and id. Only one of these is the handle. For example, if the RHS E+T were chosen to be rewritten in this sentential form, the resulting sentential form would be E * id, but E * id is not a legal right sentential form for the given grammar.

The handle of a right sentential form is unique. The task of a bottom-up parser is to find the handle of any given right sentential form that can be generated by its associated grammar. Formally, handle is defined as follows:

- Definition: β is the **handle** of the right sentential form γ=αβw if and only if S => *rm αAw =>rmαβw

In this definition, =>rm specifies a rightmost derivation step, and => *rm specifies zero or more rightmost derivation steps. Although the definition of a handle is mathematically concise, it provides little help in finding the handle of a given right sentential form. In the following, we provide the definitions of several substrings of sentential forms that are related to handles. The purpose of these is to provide some intuition about handles.

- Definition: β is a **phrase** of the right sentential form γ if and only if S =>* γ=α1Aα2 =>+α1βα2

In this definition, =>+ means one or more derivation steps.

- Definition: β is a **simple phrase** of the right sentential form γ if and only if S =>* γ=α1Aα2 =>+α1βα2

If these two definitions are compared carefully, it is clear that they differ only in the last derivation specification. The definition of phrase uses one or more steps, while the definition of simple phrase uses exactly one step.

The definitions of phrase and simple phrase may appear to have the same lack of practical value as that of a handle, but that is not true. Consider what a phrase is relative to a parse tree. It is the string of all of the leaves of the partial parse tree that is rooted at one particular internal node of the whole parse tree. A simple phrase is just a phrase that takes a single derivation step from its root nonterminal node. In terms of a parse tree, a phrase can be derived from a single nonterminal in one or more tree levels, but a simple phrase can be derived in just a single tree level. Consider the parse tree shown in Figure 4.3.

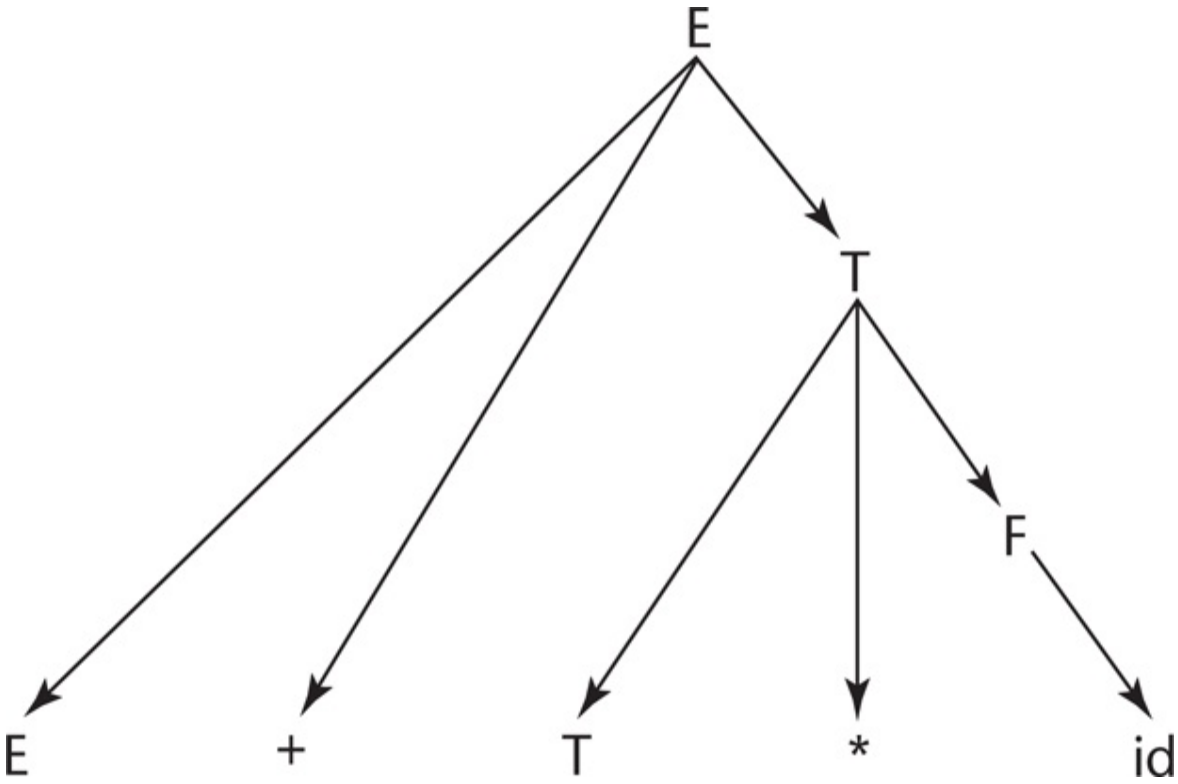

Figure 4.3 A parse tree for E+T * id

The leaves of the parse tree in Figure 4.3 comprise the sentential form E+T * id. Because there are three internal nodes, there are three phrases. Each internal node is the root of a subtree, whose leaves are a phrase. The root node of the whole parse tree, E, generates all of the resulting sentential form, E+T * id, which is a phrase. The internal node, T, generates the leaves T * id, which is another phrase. Finally, the internal node, F, generates id, which is also a phrase. So, the phrases of the sentential form E+T * id are E+T * id, and id. Notice that phrases are not necessarily RHSs in the underlying grammar.

The simple phrases are a subset of the phrases. In the previous example, the only simple phrase is id. A simple phrase is always a RHS in the grammar.

The reason for discussing phrases and simple phrases is this: The handle of

any rightmost sentential form is its leftmost simple phrase. So now we have a highly intuitive way to find the handle of any right sentential form, assuming we have the grammar and can draw a parse tree. This approach to finding handles is of course not practical for a parser. (If you already have a parse tree, why do you need a parser?) Its only purpose is to provide the reader with some intuitive feel for what a handle is, relative to a parse tree, which is easier than trying to think about handles in terms of sentential forms.

We can now consider bottom-up parsing in terms of parse trees, although the purpose of a parser is to produce a parse tree. Given the parse tree for an entire sentence, you easily can find the handle, which is the first thing to rewrite in the sentence to get the previous sentential form. Then the handle can be pruned from the parse tree and the process repeated. Continuing to the root of the parse tree, the entire rightmost derivation can be constructed.

4.5.2 Shift-Reduce Algorithms

Bottom-up parsers are often called **shift-reduce algorithms**, because shift and reduce are the two most common actions they specify. An integral part of every bottom-up parser is a stack. As with other parsers, the input to a bottom-up parser is the stream of tokens of a program and the output is a sequence of grammar rules. The shift action moves the next input token onto the parser's stack. A reduce action replaces an RHS (the handle) on top of the parser's stack by its corresponding LHS. Every parser for a programming language is a **pushdown automaton** (**PDA**), because a PDA is a recognizer for a context-free language. You need not be intimate with PDAs to understand how a bottom-up parser works, although it helps. A PDA is a very simple mathematical machine that scans strings of symbols from left to right. A PDA is so named because it uses a pushdown stack as its memory. PDAs can be used as recognizers for context-free languages. Given a string of symbols over the alphabet of a context-free language, a PDA that is designed for the purpose can determine whether the string is or is not a sentence in the language. In the process, the PDA can produce the information needed to construct a parse tree for the sentence.

With a PDA, the input string is examined, one symbol at a time, left to right.

The input is treated very much as if it were stored in another stack, because the PDA never sees more than the leftmost symbol of the input.

Note that a recursive-descent parser is also a PDA. In that case, the stack is that of the run-time system, which records subprogram calls (among other things), which correspond to the nonterminals of the grammar.

4.5.3 LR Parsers

Many different bottom-up parsing algorithms have been devised. Most of them are variations of a process called LR. LR parsers use a relatively small program and a parsing table that is built for a specific programming language. The original LR algorithm was designed by Donald Knuth (Knuth, 1965). This algorithm, which is sometimes called **canonical LR**, was not used in the years immediately following its publication because producing the required parsing table required large amounts of computer time and memory. Subsequently, several variations on the canonical LR table construction process were developed (DeRemer, 1971; DeRemer and Pennello, 1982). These are characterized by two properties: (1) They require far less computer resources to produce the required parsing table than the canonical LR algorithm, and (2) they work on smaller classes of grammars than the canonical LR algorithm.

There are three advantages to LR parsers:

1. They can be built for all programming languages.

2. They can detect syntax errors as soon as it is possible in a left-to-right scan.

3. The LR class of grammars is a proper superset of the class parsable by LL parsers (for example, many left recursive grammars are LR, but none are LL).

The only disadvantage of LR parsing is that it is difficult to produce by hand the parsing table for a given grammar for a complete programming language.

This is not a serious disadvantage, however, for there are several programs available that take a grammar as input and produce the parsing table, as - discussed later in this section.

Prior to the appearance of the LR parsing algorithm, there were a number of parsing algorithms that found handles of right sentential forms by looking both to the left and to the right of the substring of the sentential form that was suspected of being the handle. Knuth's insight was that one could effectively look to the left of the suspected handle all the way to the bottom of the parse stack to determine whether it was the handle. But all of the information in the parse stack that was relevant to the parsing process could be represented by a single state, which could be stored on the top of the stack. In other words, Knuth discovered that regardless of the length of the input string, the length of the sentential form, or the depth of the parse stack, there were only a relatively small number of different situations, as far as the parsing process is concerned. Each situation could be represented by a state and stored in the parse stack, one state symbol for each grammar symbol on the stack. At the top of the stack would always be a state symbol, which represented the relevant information from the entire history of the parse, up to the current time. We will use subscripted uppercase S's to represent the parser states.

Figure 4.4 shows the structure of an LR parser. The contents of the parse stack for an LR parser have the following form:

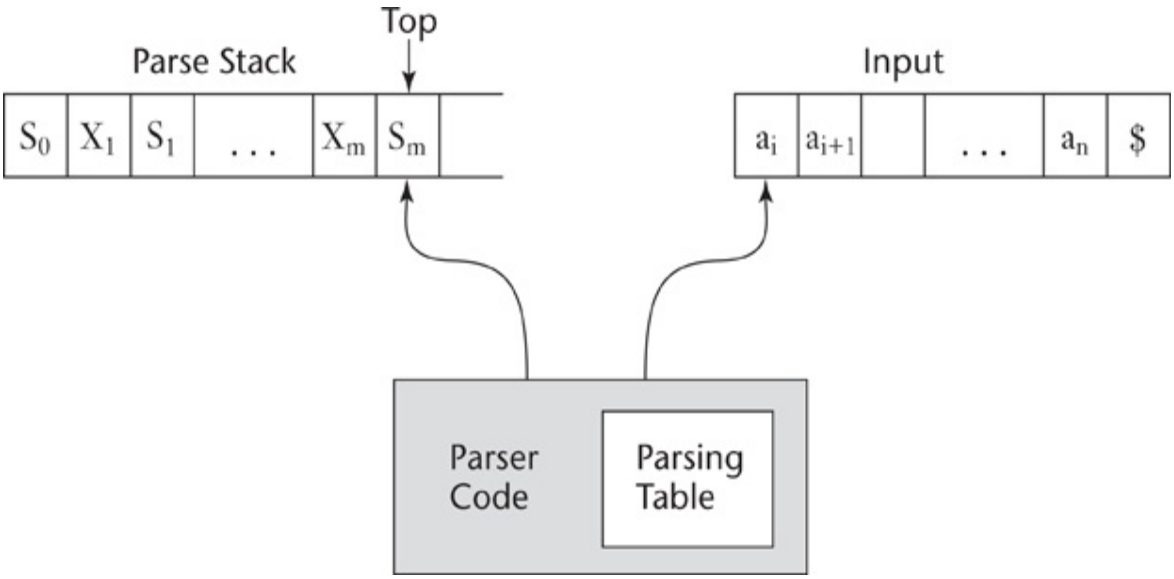

Figure 4.4 The structure of an LR parser

Figure 4.4 Full Alternative Text

S0X1S1X2…XmSm (top)

where the S's are state symbols and the X's are grammar symbols. An LR parser configuration is a pair of strings (stack, input), with the detailed form

(S0X1S1X2S2…XmSm, aiAi+1…an$)

Notice that the input string has a dollar sign at its right end. This sign is put there during initialization of the parser. It is used for normal termination of the parser. Using this parser configuration, we can formally define the LR parser process, which is based on the parsing table.

An LR parsing table has two parts, named ACTION and GOTO. The ACTION part of the table specifies most of what the parser does. It has state symbols as its row labels and the terminal symbols of the grammar as its column labels. Given a current parser state, which is represented by the state symbol on top of the parse stack, and the next symbol (token) of input, the parse table specifies what the parser should do. The two primary parser actions are shift and reduce. Either the parser shifts the next input symbol onto the parse stack, along with a state symbol, or it already has the handle on top of the stack, which it reduces to the LHS of the rule whose RHS is the same as the handle. Two other actions are possible: accept, which means the parser has successfully completed the parse of the input, and error, which means the parser has detected a syntax error.

The rows of the GOTO part of the LR parsing table have state symbols as labels. This part of the table has nonterminals as column labels. The values in the GOTO part of the table indicate which state symbol should be pushed onto the parse stack after a reduction has been completed, which means the handle has been removed from the parse stack and the new nonterminal has been pushed onto the parse stack. The specific symbol is found at the row

whose label is the state symbol on top of the parse stack after the handle and its associated state symbols have been removed. The column of the GOTO table that is used is the one with the label, that is the LHS of the rule used in the reduction.

Consider the traditional grammar for arithmetic expressions that follows:

1. $E \rightarrow E + T$
2. $E \rightarrow T$
3. $T \rightarrow T * F$
4. $T \rightarrow F$
5. $F \rightarrow (E)$
6. $F \rightarrow id$

The rules of this grammar are numbered to provide a simple way to reference them in a parsing table.

Figure 4.5 shows the LR parsing table for this grammar. Abbreviations are used for the actions: R for reduce and S for shift. R4 means reduce using rule 4; S6 means shift the next symbol of input onto the stack and push state 6 onto the stack. Empty positions in the ACTION table indicate syntax errors. In a complete parser, these could have calls to error-handling routines.

	Action						Goto		
State	id	+	*	(	)	$	E	T	F
0	S5			S4			1	2	3
1		S6				accept			
2		R2	S7		R2	R2			
3		R4	R4		R4	R4			
4	S5			S4			8	2	3
5		R6	R6		R6	R6			
6	S5			S4				9	3
7	S5			S4					10
8		S6			S11				
9		R1	S7		R1	R1			
10		R3	R3		R3	R3			
11		R5	R5		R5	R5			

Figure 4.5 The LR parsing table for an arithmetic expression grammar

Figure 4.5 Full Alternative Text

LR parsing tables can easily be constructed using a software tool, such as yacc (Johnson, 1975), which takes the grammar as input. Although LR parsing tables can be produced by hand, for a grammar of a real programming language, the task would be lengthy, tedious, and error prone. For real compilers, LR parsing tables are always generated with software

tools.

The initial configuration of an LR parser is

(S0, a1…an$)

The parser actions are informally defined as follows:

1. The Shift process is simple: The next symbol of input is pushed onto the stack, along with the state symbol that is part of the Shift specification in the ACTION table.

2. For a Reduce action, the handle must be removed from the stack. Because for every grammar symbol on the stack there is a state symbol, the number of symbols removed from the stack is twice the number of symbols in the handle. After removing the handle and its associated state symbols, the LHS of the rule is pushed onto the stack. Finally, the GOTO table is used, with the row label being the symbol that was exposed when the handle and its state symbols were removed from the stack, and the column label being the nonterminal that is the LHS of the rule used in the reduction.

3. When the action is Accept, the parse is complete and no errors were found.

4. When the action is Error, the parser calls an error-handling routine.

Although there are many parsing algorithms based on the LR concept, they differ only in the construction of the parsing table. All LR parsers use this same parsing algorithm.

Perhaps the best way to become familiar with the LR parsing process is through an example. Initially, the parse stack has the single symbol 0, which represents state 0 of the parser. The input contains the input string with an end marker, in this case a dollar sign, attached to its right end. At each step, the parser actions are dictated by the top (rightmost in Figure 4.4) symbol of the parse stack and the next (leftmost in Figure 4.4) token of input. The correct action is chosen from the corresponding cell of the ACTION part of

the parse table. The GOTO part of the parse table is used after a reduction action. Recall that GOTO is used to determine which state symbol is placed on the parse stack after a reduction.

Following is a trace of a parse of the string id + id * id, using the LR parsing algorithm and the parsing table shown in Figure 4.5.

Stack	*Input*	*Action*
0	id + id * id $	Shift 5
0id5	+ id * id $	Reduce 6 (use GOTO[0, F])
0F3	+ id * id $	Reduce 4 (use GOTO[0, T])
0T2	+ id * id $	Reduce 2 (use GOTO[0, E])
0E1	+ id * id $	Shift 6
0E1+6	id * id $	Shift 5
0E1+6id5	* id $	Reduce 6 (use GOTO[6, F])
0E1+6F3	* id $	Reduce 4 (use GOTO[6, T])
0E1+6T9	* id $	Shift 7
0E1+6T9*7	id $	Shift 5
0E1+6T9*7id5	$	Reduce 6 (use GOTO[7, F])
0E1+6T9*7F10	$	Reduce 3 (use GOTO[6, T])
0E1+6T9	$	Reduce 1 (use GOTO[0, E])
0E1	$	Accept

The algorithms to generate LR parsing tables from given grammars, which are described in Aho et al. (2006), are not overly complex but are beyond the scope of a book on programming languages. As stated previously, there are a number of different software systems available to generate LR parsing tables.

SUMMARY

Syntax analysis is a common part of language implementation, regardless of the implementation approach used. Syntax analysis is normally based on a formal syntax description of the language being implemented. A context-free grammar, which is also called BNF, is the most common approach for describing syntax. The task of syntax analysis is usually divided into two parts: lexical analysis and syntax analysis. There are several reasons for separating lexical analysis—namely, simplicity, efficiency, and portability.

A lexical analyzer is a pattern matcher that isolates the small-scale parts of a program, which are called lexemes. Lexemes occur in categories, such as integer literals and names. These categories are called tokens. Each token is assigned a numeric code, which along with the lexeme is what the lexical analyzer produces. There are three distinct approaches to constructing a lexical analyzer: using a software tool to generate a table for a table-driven analyzer, building such a table by hand, and writing code to implement a state diagram description of the tokens of the language being implemented. The state diagram for tokens can be reasonably small if character classes are used for transitions, rather than having transitions for every possible character from every state node. Also, the state diagram can be simplified by using a table lookup to recognize reserved words.

Syntax analyzers have two goals: to detect syntax errors in a given program and to produce a parse tree, or possibly only the information required to build such a tree, for a given program. Syntax analyzers are either top-down, meaning they construct leftmost derivations and a parse tree in top-down order, or bottom-up, in which case they construct the reverse of a rightmost derivation and a parse tree in bottom-up order. Parsers that work for all unambiguous grammars have complexity O(n3). However, parsers used for implementing syntax analyzers for programming languages work on subclasses of unambiguous grammars and have complexity O(n).

A recursive-descent parser is an LL parser that is implemented by writing code directly from the grammar of the source language. EBNF is ideal as the

basis for recursive-descent parsers. A recursive-descent parser has a subprogram for each nonterminal in the grammar. The code for a given grammar rule is simple if the rule has a single RHS. The RHS is examined left to right. For each nonterminal, the code calls the associated subprogram for that nonterminal, which parses whatever the nonterminal generates. For each terminal, the code compares the terminal with the next token of input. If they match, the code simply calls the lexical analyzer to get the next token. If they do not, the subprogram reports a syntax error. If a rule has more than one RHS, the subprogram must first determine which RHS it should parse. It must be possible to make this determination on the basis of the next token of input.

Two distinct grammar characteristics prevent the construction of a recursive-descent parser based on the grammar. One of these is left recursion. The process of eliminating direct left recursion from a grammar is relatively simple. Although we do not cover it, an algorithm exists to remove both direct and indirect left recursion from a grammar. The other problem is detected with the pairwise disjointness test, which tests whether a parsing subprogram can determine which RHS is being parsed on the basis of the next token of input. Some grammars that fail the pairwise disjointness test often can be modified to pass it, using left factoring.

The parsing problem for bottom-up parsers is to find the substring of the current sentential form that must be reduced to its associated LHS to get the next (previous) sentential form in the rightmost derivation. This substring is called the handle of the sentential form. A parse tree can provide an intuitive basis for recognizing a handle. A bottom-up parser is a shift-reduce algorithm, because in most cases it either shifts the next lexeme of input onto the parse stack or reduces the handle that is on top of the stack.

The LR family of shift-reduce parsers is the most commonly used bottom-up parsing approach for programming languages, because parsers in this family have several advantages over alternatives. An LR parser uses a parse stack, which contains grammar symbols and state symbols to maintain the state of the parser. The top symbol on the parse stack is always a state symbol that represents all of the information in the parse stack that is relevant to the parsing process. LR parsers use two parsing tables: ACTION and GOTO.

The ACTION part specifies what the parser should do, given the state symbol on top of the parse stack and the next token of input. The GOTO table is used to determine which state symbol should be placed on the parse stack after a reduction has been done.

REVIEW QUESTIONS

1. What are three reasons why syntax analyzers are based on grammars?
2. Explain the three reasons why lexical analysis is separated from syntax analysis.
3. Define *lexeme* and *token*.
4. What are the primary tasks of a lexical analyzer?
5. Describe briefly the three approaches to building a lexical analyzer.
6. What is a state transition diagram?
7. Why are character classes used, rather than individual characters, for the letter and digit transitions of a state diagram for a lexical analyzer?
8. What are the two distinct goals of syntax analysis?
9. Describe the differences between top-down and bottom-up parsers.
10. Describe the parsing problem for a top-down parser.
11. Describe the parsing problem for a bottom-up parser.
12. Explain why compilers use parsing algorithms that work on only a subset of all grammars.
13. Why are named constants used, rather than numbers, for token codes?
14. Describe how a recursive-descent parsing subprogram is written for a rule with a single RHS.
15. Explain the two grammar characteristics that prohibit them from being used as the basis for a top-down parser.

16. What is the FIRST set for a given grammar and sentential form?
17. Describe the pairwise disjointness test.
18. What is left factoring?
19. What is a phrase of a sentential form?
20. What is a simple phrase of a sentential form?
21. What is the handle of a sentential form?
22. What is the mathematical machine on which both top-down and bottom-up parsers are based?
23. Describe three advantages of LR parsers.
24. What was Knuth’s insight in developing the LR parsing technique?
25. Describe the purpose of the ACTION table of an LR parser.
26. Describe the purpose of the GOTO table of an LR parser.
27. Is left recursion a problem for LR parsers?

PROBLEM SET

1. Perform the pairwise disjointness test for the following grammar rules.

    1. A → aB | b | cBB

    2. B → aB | bA | aBb

    3. C → aaA | b | caB

2. Perform the pairwise disjointness test for the following grammar rules.

    1. S → aSb | bAA

    2. A → B{aB} | a

    3. B → aB | a

3. Show a trace of the recursive descent parser given in Section 4.4.1 for the string `a + b * c`.

4. Show a trace of the recursive descent parser given in Section 4.4.1 for the string `a * (b + c)`.

5. Given the following grammar and the right sentential form, draw a parse tree and show the phrases and simple phrases, as well as the handle.

    S → aAb | bBAA → ab | aABB → aB | b

    1. aaAbb

    2. bBab

    3. aaAbBb

6. Given the following grammar and the right sentential form, draw a parse tree and show the phrases and simple phrases, as well as the handle.

S → AbB | bAcA → Ab | aBBB → Ac | cBb | c

1. aAcccbbc
2. AbcaBccb
3. baBcBbbc

7. Show a complete parse, including the parse stack contents, input string, and action for the string id * (id + id), using the grammar and parse table in Section 4.5.3.

8. Show a complete parse, including the parse stack contents, input string, and action for the string (id + id) * id, using the grammar and parse table in Section 4.5.3.

9. Get the algorithm to remove the indirect left recursion from a grammar from Aho et al. (2006). Use this algorithm to remove all left recursion from the following grammar: S → Aa | BbA → Aa | Abc | c | SbB → bb

PROGRAMMING EXERCISES

1. Design a state diagram to recognize one form of the comments of the C-based programming languages, those that begin with `/*` and end with `*/`.

2. Design a state diagram to recognize the floating-point literals of your favorite programming language.

3. Write and test the code to implement the state diagram of Problem 1.

4. Write and test the code to implement the state diagram of Problem 2.

5. Modify the lexical analyzer given in Section 4.2 to recognize the following list of reserved words and return their respective token codes: **`for`** (`FOR_CODE`, `30`), **`if`** (`IF_CODE`, `31`), **`else`** (`ELSE_CODE`, `32`), **`while`** (`WHILE_CODE`, `33`), **`do`** (`DO_CODE`, `34`), **`int`** (`INT_CODE`, `35`), **`float`** (`FLOAT_CODE`, `36`), **`switch`** (`SWITCH_CODE`, `37`).

6. Convert the lexical analyzer (which is written in C) given in Section 4.2 to Java.

7. Convert the recursive descent parser routines for <expr>, <term>, and <factor> given in Section 4.4.1 to Java.

8. For those rules that pass the test in Problem 1, write a recursive-descent parsing subprogram that parses the language generated by the rules. Assume you have a lexical analyzer named `lex` and an error-handling subprogram named `error`, which is called whenever a syntax error is detected.

9. For those rules that pass the test in Problem 2, write a recursive-descent parsing subprogram that parses the language generated by the rules. Assume you have a lexical analyzer named `lex` and an error-handling subprogram named `error`, which is called whenever a syntax error is detected.

10. Implement and test the LR parsing algorithm given in Section 4.5.3.

11. Write an EBNF rule that describes the **`while`** statement of Java or C++. Write the recursive-descent subprogram in Java or C++ for this rule.

12. Write an EBNF rule that describes the **`for`** statement of Java or C++. Write the recursive-descent subprogram in Java or C++ for this rule.

5 Names, Bindings, and Scopes

This chapter introduces the fundamental semantic issues of variables. It begins by describing the nature of names and special words in programming languages. The attributes of variables, including type, address, and value, are then discussed, including the issue of aliases. The important concepts of binding and binding times are introduced next, including the different possible binding times for variable attributes and how they define four different categories of variables. Following that, two very different scoping rules for names, static and dynamic, are described, along with the concept of a referencing environment of a statement. Finally, named constants and variable initialization are discussed.

5.1 Introduction

Imperative programming languages are, to varying degrees, abstractions of the underlying von Neumann computer architecture. The architecture's two primary components are its memory, which stores both instructions and data, and its processor, which provides operations for modifying the contents of the memory. The abstractions in a language for the memory cells of the machine are variables. In some cases, the characteristics of the abstractions are very close to the characteristics of the cells; an example of this is an integer variable, which is usually represented directly in one or more bytes of memory. In other cases, the abstractions are far removed from the organization of the hardware memory, as with a three-dimensional array, which requires a software mapping function to support the abstraction.

A variable can be characterized by a collection of properties, or attributes, the most important of which is type, a fundamental concept in programming languages. Designing the data types of a language requires that a variety of issues be considered. (Data types are discussed in Chapter 6.) Among the most important of these issues are the scope and lifetime of variables.

Functional programming languages allow expressions to be named. These named expressions appear like assignments to variable names in imperative languages, but are fundamentally different in that they cannot be changed. So, they are like the named constants of the imperative languages. Pure functional languages do not have variables that are like those of the imperative languages. However, many functional languages do include such variables.

In the remainder of this book, families of languages will often be referred to as if they were single languages. For example, Fortran will mean all of the versions of Fortran. This is also the case for Ada. Likewise, a reference to C will mean the original version of C, as well as C89 and C99. When a specific version of a language is named, it is because it is different from the other family members within the topic being discussed. If we add a plus sign (+) to the name of a version of a language, we mean all versions of the language

beginning with the one named. For example, Fortran 95+ means all versions of Fortran beginning with Fortran 95. The phrase **C-based languages** will be used to refer to C, Objective-C, C++, Java, and C#.1

1. We were tempted to include the scripting languages JavaScript and PHP as C-based languages, but decided they were just a bit too different from their ancestors.

5.2 Names

Before beginning our discussion of variables, the design of one of the fundamental attributes of variables, names, must be covered. Names are also associated with subprograms, formal parameters, and other program constructs. The term *identifier* is often used interchangeably with *name*.

5.2.1 Design Issues

The following are the primary design issues for names:

- Are names case sensitive?
- Are the special words of the language reserved words or keywords?

These issues are discussed in the following two subsections, which also include examples of several design choices.

5.2.2 Name Forms

A **name** is a string of characters used to identify some entity in a program.

C99 has no length limitation on its internal names, but only the first 63 are significant. External names in C99 (those defined outside functions, which must be handled by the linker) are restricted to 31 characters. Names in Java and C# have no length limit, and all characters in them are significant. C++ does not specify a length limit on names, although implementors sometimes do.

Names in most programming languages have the same form: a letter followed by a string consisting of letters, digits, and underscore characters (_). Although the use of underscore characters to form names was widely used in

the 1970s and 1980s, that practice is now far less popular. In the C-based languages, it has to a large extent been replaced by the so-called *camel notation*, in which all of the words of a multiple-word name except the first are capitalized, as in `myStack`.[2] Note that the use of underscores and mixed case in names is a programming style issue, not a language design issue.

2. It is called “camel” because words written in it often have embedded uppercase letters, which look like a camel’s humps.

history note

The earliest programming languages used single-character names. This notation was natural because early programming was primarily mathematical, and mathematicians have long used single-character names for unknowns in their formal notations.

Fortran I broke with the tradition of the single-character name, allowing up to six characters in its names.

All variable names in PHP must begin with a dollar sign. In Perl, the special character at the beginning of a variable’s name, `$`, `@`, or `%`, specifies its type (although in a different sense than in other languages). In Ruby, special characters at the beginning of a variable’s name, `@` or `@@`, indicate that the variable is an instance or a class variable, respectively.

In many languages, notably the C-based languages, uppercase and lowercase letters in names are distinct; that is, names in these languages are **case sensitive**. For example, the following three names are distinct in C++: `rose`, `ROSE`, and `Rose`. To some people, this is a serious detriment to readability, because names that look very similar in fact denote different entities. In that sense, case sensitivity violates the design principle that language constructs that look similar should have similar meanings. But in languages whose variable names are case-sensitive, although `Rose` and `rose` look similar, there is no connection between them.

Obviously, not everyone agrees that case sensitivity is bad for names. In C,

the problems of case sensitivity are avoided by the convention that variable names do not include uppercase letters. In Java and C#, however, the problem cannot be escaped because many of the predefined names include both uppercase and lowercase letters. For example, the Java method for converting a string to an integer value is `parseInt`, and spellings such as `ParseInt` and `parseint` are not recognized. This is a problem of writability rather than readability, because the need to remember specific case usage makes it more difficult to write correct programs. It is a kind of intolerance on the part of the language designer, which is enforced by the compiler.

5.2.3 Special Words

Special words in programming languages are used to make programs more readable by naming actions to be performed. They also are used to separate the syntactic parts of statements and programs. In most languages, special words are classified as reserved words, which means they cannot be redefined by programmers. But in some, such as Fortran, they are only keywords, which means they can be redefined.

A **reserved word** is a special word of a programming language that cannot be used as a name. There is one potential problem with reserved words: If the language includes a large number of reserved words, the user may have difficulty making up names that are not reserved. The best example of this is COBOL, which has 300 reserved words. Unfortunately, some of the most commonly chosen names by programmers are in the list of reserved words—for example, `LENGTH`, `BOTTOM`, `DESTINATION`, and `COUNT`.

In program code examples in this book, reserved words are presented in boldface.

In most languages, names that are defined in other program units, such as Java packages and C and C++ libraries, can be made visible to a program. These names are predefined, but visible only if explicitly imported. Once imported, they cannot be redefined.

5.3 Variables

A program variable is an abstraction of a computer memory cell or collection of cells. Programmers often think of variables as names for memory locations, but there is much more to a variable than just a name.

The move from machine languages to assembly languages was largely one of replacing absolute numeric memory addresses for data with names, making programs far more readable and therefore easier to write and maintain. Assembly languages also provided an escape from the problem of manual absolute addressing, because the translator that converted the names to actual addresses also chose those addresses.

A variable can be characterized as a sextuple of attributes: (name, address, value, type, lifetime, and scope). Although this may seem too complicated for such an apparently simple concept, it provides the clearest way to explain the various aspects of variables.

Our discussion of variable attributes will lead to examinations of the important related concepts of aliases, binding, binding times, declarations, scoping rules, and referencing environments.

The name, address, type, and value attributes of variables are discussed in the following subsections. The lifetime and scope attributes are discussed in Sections 5.4.3 and 5.5, respectively.

5.3.1 Name

Variable names are the most common names in programs. They were discussed at length in Section 5.2 in the general context of entity names in programs. Most variables have names. The ones that do not are discussed in Section 5.4.3.3.

5.3.2 Address

The **address** of a variable is the machine memory address with which it is associated. This association is not as simple as it may appear. In many languages, it is possible for the same variable to be associated with different addresses at different times during the execution of the program. For example, if a subprogram has a local variable that is allocated from the run-time stack when the subprogram is called, different calls may result in that variable having different addresses. These are in a sense different instantiations of the same variable.

The process of associating variables with addresses is further discussed in Section 5.4.3. An implementation model for subprograms and their activations is discussed in Chapter 10.

The address of a variable is sometimes called its **l-value**, because the address is what is required when the name of a variable appears in the left side of an assignment.

It is possible to have multiple variables that have the same address. When more than one variable name can be used to access the same memory location, the variables are called **aliases**. Aliasing is a hindrance to readability because it allows a variable to have its value changed by an assignment to a different variable. For example, if variables named `total` and `sum` are aliases, any change to the value of `total` also changes the value of `sum` and vice versa. A reader of the program must always remember that `total` and `sum` are different names for the same memory cell. Because there can be any number of aliases in a program, this can be very difficult in practice. Aliasing also makes program verification more difficult.

Aliases can be created in programs in several different ways. One common way in C and C++ is with their union types. Unions are discussed at length in Chapter 6.

Two pointer variables are aliases when they point to the same memory location. The same is true for reference variables. This kind of aliasing is

simply a side effect of the nature of pointers and references. When a C++ pointer is set to point at a named variable, the pointer, when dereferenced, and the variable's name are aliases.

Aliasing can be created in many languages through subprogram parameters. These kinds of aliases are discussed in Chapter 9.

The time when a variable becomes associated with an address is very important to an understanding of programming languages. This subject is discussed in Section 5.4.3.

5.3.3 Type

The **type** of a variable determines the range of values the variable can store and the set of operations that are defined for values of the type. For example, the `int` type in Java specifies a value range of −2147483648 to 2147483647 and arithmetic operations for addition, subtraction, multiplication, division, and modulus.

5.3.4 Value

The **value** of a variable is the contents of the memory cell or cells associated with the variable. It is convenient to think of computer memory in terms of *abstract* cells, rather than physical cells. The physical cells, or individually addressable units, of most contemporary computer memories are eight-bit units called bytes. A byte size is too small for most program variables. An abstract memory cell has the size required by the variable with which it is associated. For example, although floating-point values may occupy four physical bytes in a particular implementation of a particular language, a floating-point value is thought of as occupying a single abstract memory cell. The value of each simple nonstructured type is considered to occupy a single abstract cell. Henceforth, the term *memory cell* will mean abstract memory cell.

A variable's value is sometimes called its **r-value** because it is what is

required when the name of the variable appears in the right side of an assignment statement. To access the *r*-value, the *l*-value must be determined first. Such determinations are not always simple. For example, scoping rules can greatly complicate matters, as is discussed in Section 5.5.

5.4 The Concept of Binding

A **binding** is an association between an attribute and an entity, such as between a variable and its type or value, or between an operation and a symbol. The time at which a binding takes place is called **binding time**. Binding and binding times are prominent concepts in the semantics of programming languages. Bindings can take place at language design time, language implementation time, compile time, load time, link time, or run time. For example, the asterisk symbol (`*`) is usually bound to the multiplication operation at language design time. A data type, such as **`int`** in C, is bound to a range of possible values at language implementation time. At compile time, a variable in a Java program is bound to a particular data type. A variable may be bound to a storage cell when the program is loaded into memory. That same binding does not happen until run time in some cases, as with variables declared in Java methods. A call to a library subprogram is bound to the subprogram code at link time.

Consider the following C++ assignment statement:

```
count = count + 5;
```

Some of the bindings and their binding times for the parts of this assignment statement are as follows:

- The type of `count` is bound at compile time.
- The set of possible values of `count` is bound at compiler design time.
- The meaning of the operator symbol + is bound at compile time, when the types of its operands have been determined.
- The internal representation of the literal `5` is bound at compiler design time.
- The value of `count` is bound at execution time with this statement.

A complete understanding of the binding times for the attributes of program entities is a prerequisite for understanding the semantics of a programming language. For example, to understand what a subprogram does, one must understand how the actual parameters in a call are bound to the formal parameters in its definition. To determine the current value of a variable, it may be necessary to know when the variable was bound to storage and with which statement or statements.

5.4.1 Binding of Attributes to Variables

A binding is **static** if it first occurs before run time begins and remains unchanged throughout program execution. If the binding first occurs during run time or can change in the course of program execution, it is called **dynamic**. The physical binding of a variable to a storage cell in a virtual memory environment is complex, because the page or segment of the address space in which the cell resides may be moved in and out of memory many times during program execution. In a sense, such variables are bound and unbound repeatedly. These bindings, however, are maintained by computer hardware, and the changes are invisible to the program and the user. Because they are not important to the discussion, we are not concerned with these hardware bindings. The essential point is to distinguish between static and dynamic bindings.

5.4.2 Type Bindings

Before a variable can be referenced in a program, it must be bound to a data type. The two important aspects of this binding are how the type is specified and when the binding takes place. Types can be specified statically through some form of explicit or implicit declaration.

5.4.2.1 Static Type Binding

An **explicit declaration** is a statement in a program that lists variable names and specifies that they are a particular type. An **implicit declaration** is a means of associating variables with types through default conventions, rather than declaration statements. In this case, the first appearance of a variable name in a program constitutes its implicit declaration. Both explicit and implicit declarations create static bindings to types.

Most widely used programming languages that use static type binding exclusively and were designed since the mid-1960s require explicit declarations of all variables (Visual Basic, ML, C#, and Swift are some exceptions).

Implicit variable type binding is done by the language processor, either a compiler or an interpreter. There are several different bases for implicit variable type bindings. The simplest of these is naming conventions. In this case, the compiler or interpreter binds a variable to a type based on the syntactic form of the variable's name.

Although they are a minor convenience to programmers, implicit declarations can be detrimental to reliability because they prevent the compilation process from detecting some typographical and programmer errors.

Some of the problems with implicit declarations can be avoided by requiring names for specific types to begin with particular special characters. For example, in Perl any name that begins with `$` is a scalar, which can store either a string or a numeric value. If a name begins with `@`, it is an array; if it begins with a `%`, it is a hash structure.3 This creates different namespaces for different type variables. In this scenario, the names `@apple` and `%apple` are unrelated, because each is from a different namespace. Furthermore, a program reader always knows the type of a variable when reading its name.

3. Both arrays and hashes are considered types—both can store any scalar in their elements.

Another kind of implicit type declarations uses context. This is sometimes called **type inference**. In the simpler case, the context is the type of the value assigned to the variable in a declaration statement. For example, in C# a **`var`** declaration of a variable must include an initial value, whose type is taken as

the type of the variable. Consider the following declarations:

```
var sum = 0;
var total = 0.0;
var name = "Fred";
```

The types of `sum`, `total`, and `name` are **`int`**, **`float`**, and **`string`**, respectively. Keep in mind that these are statically typed variables—their types are fixed for the lifetime of the unit in which they are declared.

Visual Basic, Swift, and the functional languages ML, Haskell, OCaml, and F# also use type inferencing.

5.4.2.2 Dynamic Type Binding

With dynamic type binding, the type of a variable is not specified by a declaration statement, nor can it be determined by the spelling of its name. Instead, the variable is bound to a type when it is assigned a value in an assignment statement. When the assignment statement is executed, the variable being assigned is bound to the type of the value of the expression on the right side of the assignment. Such an assignment may also bind the variable to an address and a memory cell, because different type values may require different amounts of storage. Any variable can be assigned any type value. Furthermore, a variable's type can change any number of times during program execution. It is important to realize that the type of a variable whose type is dynamically bound may be temporary.

When the type of a variable is statically bound, the name of the variable can be thought of being bound to a type, in the sense that the type and name of a variable are simultaneously bound. However, when a variable's type is dynamically bound, its name can be thought of as being only temporarily bound to a type. In reality, the names of variables are never bound to types. Names can be bound to variables and variables can be bound to types.

Languages in which types are dynamically bound are dramatically different from those in which types are statically bound. The primary advantage of dynamic binding of variables to types is that it provides more programming

flexibility. For example, a program to process numeric data in a language that uses dynamic type binding can be written as a generic program, meaning that it is capable of dealing with data of any numeric type. Whatever type data is input will be acceptable, because the variables in which the data are to be stored can be bound to the correct type when the data is assigned to the variables after input. By contrast, because of static binding of types, one cannot write a C program to process data without knowing the type of that data.

Before the mid-1990s, the most commonly used programming languages used static type binding, the primary exceptions being some functional languages such as Lisp. However, since then there has been a significant shift to languages that use dynamic type binding. In Python, Ruby, JavaScript, and PHP, type binding is dynamic. For example, a JavaScript script may contain the following statement:

```
list = [10.2, 3.5];
```

Regardless of the previous type of the variable named `list`, this assignment causes it to become the name of a single-dimensioned array of length 2. If the statement

```
list = 47;
```

followed the previous example assignment, `list` would become the name of a scalar variable.

The option of dynamic type binding was included in C# 2010. A variable can be declared to use dynamic type binding by including the **`dynamic`** reserved word in its declaration, as in the following example:

```
dynamic  any;
```

This is similar, although also different from declaring `any` to have type **`object`**. It is similar in that `any` can be assigned a value of any type, just as if it were declared **`object`**. It is different in that it is not useful for several different situations of interoperation; for example, with dynamically typed languages such as IronPython and IronRuby (.NET versions of Python and Ruby, respectively). However, it is useful when data of unknown type come

into a program from an external source. Class members, properties, method parameters, method return values, and local variables can all be declared **`dynamic`**.

In pure object-oriented languages—for example, Ruby—all variables are references and do not have types; all data are objects and any variable can reference any object. Variables in such languages are, in a sense, all the same type—they are references. However, unlike the references in Java, which are restricted to referencing one specific type of value, variables in Ruby can reference any object.

There are two disadvantages to dynamic type binding. First, it causes programs to be less reliable, because the error-detection capability of the compiler is diminished relative to a compiler for a language with static type bindings. Dynamic type binding allows any variable to be assigned a value of any type. Incorrect types of right sides of assignments are not detected as errors; rather, the type of the left side is simply changed to the incorrect type. For example, suppose that in a particular JavaScript program, `i` and `x` are currently the names of scalar numeric variables and `y` is currently the name of an array. Furthermore, suppose that the program needs the assignment statement

```
i = x;
```

but because of a keying error, it has the assignment statement

```
i = y;
```

In JavaScript (or any other language that uses dynamic type binding), no error is detected in this statement by the interpreter—the type of the variable named `i` is simply changed to an array. But later uses of `i` will expect it to be a scalar, and correct results will be impossible. In a language with static type binding, such as Java, the compiler would detect the error in the assignment `i = y`, and the program would not get to execution.

Note that this disadvantage is also present to some extent in some languages that use static type binding, such as C and C++, which in many cases automatically convert the type of the RHS of an assignment to the type of the

LHS.

Perhaps the greatest disadvantage of dynamic type binding is cost. The cost of implementing dynamic attribute binding is considerable, particularly in execution time. Type checking must be done at run time. Furthermore, every variable must have a run-time descriptor associated with it to maintain the current type. The storage used for the value of a variable must be of varying size, because different type values require different amounts of storage.

Finally, languages that have dynamic type binding for variables are usually implemented using pure interpreters rather than compilers. Computers do not have instructions whose operand types are not known at compile time. Therefore, a compiler cannot build machine instructions for the expression a + b if the types of a and b are not known at compile time. Pure interpretation typically takes at least 10 times as long as it does to execute equivalent machine code. Of course, if a language is implemented with a pure interpreter, the time to do dynamic type binding is hidden by the overall time of interpretation, so it seems less costly in that environment. On the other hand, languages with static type bindings are seldom implemented by pure interpretation, because programs in these languages can be easily translated to very efficient machine code versions.

5.4.3 Storage Bindings and Lifetime

The fundamental character of an imperative programming language is in large part determined by the design of the storage bindings for its variables. It is therefore important to have a clear understanding of these bindings.

The memory cell to which a variable is bound somehow must be taken from a pool of available memory. This process is called **allocation**. **Deallocation** is the process of placing a memory cell that has been unbound from a variable back into the pool of available memory.

The **lifetime** of a variable is the time during which the variable is bound to a

specific memory location. So, the lifetime of a variable begins when it is bound to a specific cell and ends when it is unbound from that cell. To investigate storage bindings of variables, it is convenient to separate scalar (unstructured) variables into four categories, according to their lifetimes. These categories are named static, stack-dynamic, explicit heap-dynamic, and implicit heap-dynamic. In the following sections, we discuss the definitions of these four categories, along with their purposes, advantages, and disadvantages.

5.4.3.1 Static Variables

A **static variable** is one that is bound to a memory cell before program execution begins and remains bound to that same memory cell until program execution terminates. Statically bound variables have several valuable applications in programming. Globally accessible variables are often used throughout the execution of a program, thus making it necessary to have them bound to the same storage during that execution. Sometimes it is convenient to have subprograms that are history sensitive. Such a subprogram must have local static variables.

One advantage of static variables is efficiency. All addressing of static variables can be direct;4 other kinds of variables often require indirect addressing, which is slower. Also, no run-time overhead is incurred for allocation and deallocation of static variables, although this time is often negligible.

4. In some implementations, static variables are addressed through a base register, making accesses to them as costly as for stack-allocated variables.

One disadvantage of static binding to storage is reduced flexibility; in particular, a language that has only static variables cannot support recursive subprograms. Another disadvantage is that storage cannot be shared among variables. For example, suppose a program has two subprograms, both of which require large arrays. Furthermore, suppose that the two subprograms are never active at the same time. If the arrays are static, they cannot share the same storage.

C and C++ allow programmers to include the **`static`** specifier on a variable definition in a function, making the variables it defines static. Note that when the **`static`** modifier appears in the declaration of a variable in a class definition in C++, Java, and C#, it also implies that the variable is a class variable, rather than an instance variable. Class variables are created statically some time before the class is first instantiated.

5.4.3.2 Stack-Dynamic Variables

Stack-dynamic variables are those whose storage bindings are created when their declaration statements are elaborated, but whose types are statically bound. **Elaboration** of such a declaration refers to the storage allocation and binding process indicated by the declaration, which takes place when execution reaches the code to which the declaration is attached. Therefore, elaboration occurs during run time. For example, the variable declarations that appear at the beginning of a Java method are elaborated when the method is called and the variables defined by those declarations are deallocated when the method completes its execution.

As their name indicates, stack-dynamic variables are allocated from the run-time stack.

Some languages—for example, C++ and Java—allow variable declarations to occur anywhere a statement can appear. In some implementations of these languages, all of the stack-dynamic variables declared in a function or method (not including those declared in nested blocks) may be bound to storage at the beginning of execution of the function or method, even though the declarations of some of these variables do not appear at the beginning. In such cases, the variable becomes visible at the declaration, but the storage binding (and initialization, if it is specified in the declaration) occurs when the function or method begins execution. The fact that storage binding of a variable takes place before it becomes visible does not affect the semantics of the language.

The advantages of stack-dynamic variables are as follows: To be useful, at least in most cases, recursive subprograms require some form of dynamic

local storage so that each active copy of the recursive subprogram has its own version of the local variables. These needs are conveniently met by stack-dynamic variables. Even in the absence of recursion, having stack-dynamic local storage for subprograms is not without merit, because all subprograms share the same memory space for their locals.

The disadvantages, relative to static variables, of stack-dynamic variables are the run-time overhead of allocation and deallocation, possibly slower accesses because indirect addressing is required, and the fact that subprograms cannot be history sensitive. The time required to allocate and deallocate stack-dynamic variables is not significant, because all of the stack-dynamic variables that are declared at the beginning of a subprogram are allocated and deallocated together, rather than by separate operations.

In Java, C++, and C#, variables defined in methods are by default stack dynamic.

All attributes other than storage are statically bound to stack-dynamic scalar variables. That is not the case for some structured types, as is discussed in Chapter 6. Implementation of allocation/deallocation processes for stack--dynamic variables is discussed in Chapter 10.

5.4.3.3 Explicit Heap-Dynamic Variables

Explicit heap-dynamic variables are nameless (abstract) memory cells that are allocated and deallocated by explicit run-time instructions written by the programmer. These variables, which are allocated from and deallocated to the heap, can only be referenced through pointer or reference variables. The heap is a collection of storage cells whose organization is highly disorganized due to the unpredictability of its use. The pointer or reference variable that is used to access an explicit heap-dynamic variable is created as any other scalar variable. An explicit heap-dynamic variable is created by either an operator (for example, in C++) or a call to a system subprogram provided for that purpose (for example, in C).

In C++, the allocation operator, named **new**, uses a type name as its operand. When executed, an explicit heap-dynamic variable of the operand type is created and its address is returned. Because an explicit heap-dynamic variable is bound to a type at compile time, that binding is static. However, such variables are bound to storage at the time they are created, which is during run time.

In addition to a subprogram or operator for creating explicit heap-dynamic variables, some languages include a subprogram or operator for explicitly destroying them.

As an example of explicit heap-dynamic variables, consider the following C++ code segment:

```
int  *intnode;      // Create a pointer
intnode =  new int; // Create the heap-dynamic variable
. . .
delete  intnode;   // Deallocate the heap-dynamic variable
                        // to which intnode points
```

In this example, an explicit heap-dynamic variable of **int** type is created by the **new** operator. This variable can then be referenced through the pointer, `intnode`. Later, the variable is deallocated by the **delete** operator. C++ requires the explicit deallocation operator **delete**, because it does not use implicit storage reclamation, such as garbage collection.

In Java, all data except the primitive scalars are objects. Java objects are explicitly heap dynamic and are accessed through reference variables. Java has no way of explicitly destroying a heap-dynamic variable; rather, implicit garbage collection is used. Garbage collection is discussed in Chapter 6.

C# has both explicit heap-dynamic and stack-dynamic objects, all of which are implicitly deallocated. In addition, C# supports C++-style pointers. Such pointers are used to reference heap, stack, and even static variables and objects. These pointers have the same dangers as those of C++, and the objects they reference on the heap are not implicitly deallocated. Pointers are included in C# to allow C# components to interoperate with C and C++ components. To discourage their use, and also to make clear to any program reader that the code uses pointers, the header of any method that defines a

pointer must include the reserved word **`unsafe`**.

Explicit heap-dynamic variables are often used to construct dynamic structures, such as linked lists and trees, that need to grow and/or shrink during execution. Such structures can be built conveniently using pointers or references and explicit heap-dynamic variables.

The disadvantages of explicit heap-dynamic variables are the difficulty of using pointer and reference variables correctly, the cost of references to the variables, and the complexity of the required storage management implementation. This is essentially the problem of heap management, which is costly and complicated. Implementation methods for explicit heap-dynamic variables are discussed at length in Chapter 6.

5.4.3.4 Implicit Heap-Dynamic Variables

Implicit heap-dynamic variables are bound to heap storage only when they are assigned values. In fact, all their attributes are bound every time they are assigned. For example, consider the following JavaScript assignment statement:

```
highs = [74, 84, 86, 90, 71];
```

Regardless of whether the variable named `highs` was previously used in the program or what it was used for, it is now an array of five numeric values.

The advantage of such variables is that they have the highest degree of flexibility, allowing highly generic code to be written. One disadvantage of implicit heap-dynamic variables is the run-time overhead of maintaining all the dynamic attributes, which could include array subscript types and ranges, among others. Another disadvantage is the loss of some error detection by the compiler, as discussed in Section 5.4.2.2.

5.5 Scope

One of the important factors in understanding variables is scope. The **scope** of a variable is the range of statements in which the variable is visible. A variable is **visible** in a statement if it can be referenced or assigned in that statement.

The scope rules of a language determine how a particular occurrence of a name is associated with a variable, or in the case of a functional language, how a name is associated with an expression. In particular, scope rules determine how references to variables declared outside the currently executing subprogram or block are associated with their declarations and thus their attributes (blocks are discussed in Section 5.5.2). A clear understanding of these rules for a language is therefore essential to the ability to write or read programs in that language.

A variable is **local** in a program unit or block if it is declared there. The nonlocal variables of a program unit or block are those that are visible within the program unit or block but are not declared there. Global variables are a special category of nonlocal variables, which are discussed in Section 5.5.4.

Scoping issues of classes, packages, and namespaces are discussed in Chapter 11.

5.5.1 Static Scope

ALGOL 60 introduced the method of binding names to nonlocal variables called **static scoping**,[5] which has been copied by many subsequent imperative languages and many nonimperative languages as well. Static scoping is so named because the scope of a variable can be statically determined—that is, prior to execution. This permits a human program reader (and a compiler) to determine the type of every variable in the program simply by examining its source code.

5. Static scoping is sometimes called *lexical scoping*.

There are two categories of static-scoped languages: those in which subprograms can be nested, which creates nested static scopes, and those in which subprograms cannot be nested. In the latter category, static scopes are also created by subprograms but nested scopes are created only by nested class definitions and blocks.

Ada, JavaScript, Common Lisp, Scheme, Fortran 2003+, F#, and Python allow nested subprograms, but the C-based languages do not.

Our discussion of static scoping in this section focuses on those languages that allow nested subprograms. Initially, we assume that *all* scopes are associated with program units and that all referenced nonlocal variables are declared in other program units.6 In this chapter, it is assumed that scoping is the only method of accessing nonlocal variables in the languages under discussion. This is not true for all languages. It is not even true for all languages that use static scoping, but the assumption simplifies the discussion here.

6. Nonlocal variables not defined in other program units are discussed in Section 5.5.4.

When the reader of a program finds a reference to a variable, the attributes of the variable can be determined by finding the statement in which it is declared (either explicitly or implicitly). In static-scoped languages with nested subprograms, this process can be thought of in the following way. Suppose a reference is made to a variable `x` in subprogram `sub1`. The correct declaration is found by first searching the declarations of subprogram `sub1`. If no declaration is found for the variable there, the search continues in the declarations of the subprogram that declared subprogram `sub1`, which is called its **static parent**. If a declaration of `x` is not found there, the search continues to the next-larger enclosing unit (the unit that declared `sub1`'s parent), and so forth, until a declaration for `x` is found or the largest unit's declarations have been searched without success. In that case, an undeclared variable error is reported. The static parent of subprogram `sub1`, and its static parent, and so forth up to and including the largest enclosing subprogram, are called the **static ancestors** of `sub1`. Actual implementation techniques for

static scoping, which are discussed in Chapter 10, are usually much more efficient than the process just described.

Consider the following JavaScript function, `big`, in which the two functions `sub1` and `sub2` are nested:

```
function  big() {
  function  sub1() {
    var  x = 7;
    sub2();
  }
  function  sub2() {
    var  y = x;
  }
  var  x = 3;
  sub1();
}
```

Under static scoping, the reference to the variable `x` in `sub2` is to the `x` declared in the procedure `big`. This is true because the search for `x` begins in the procedure in which the reference occurs, `sub2`, but no declaration for `x` is found there. The search continues in the static parent of `sub2`, `big`, where the declaration of `x` is found. The `x` declared in `sub1` is ignored, because it is not in the static ancestry of `sub2`.

In some languages that use static scoping, regardless of whether nested subprograms are allowed, some variable declarations can be hidden from some other code segments. For example, consider again the JavaScript function `big`. The variable `x` is declared in both `big` and in `sub1`, which is nested inside `big`. Within `sub1`, every simple reference to `x` is to the local `x`. Therefore, the outer `x` is hidden from `sub1`.

5.5.2 Blocks

Many languages allow new static scopes to be defined in the midst of executable code. This powerful concept, introduced in ALGOL 60, allows a section of code to have its own local variables whose scope is minimized. Such variables are typically stack dynamic, so their storage is allocated when the section is entered and deallocated when the section is exited. Such a

section of code is called a **block**. Blocks provide the origin of the phrase **block-structured language**.

The C-based languages allow any compound statement (a statement sequence surrounded by matched braces) to have declarations and thereby define a new scope. Such compound statements are called blocks. For example, if `list` were an integer array, one could write the following:

```
if (list[i] < list[j]) {
  int temp;
  temp = list[i];
  list[i] = list[j];
  list[j] = temp;
}
```

The scopes created by blocks, which could be nested in larger blocks, are treated exactly like those created by subprograms. References to variables in a block that are not declared there are connected to declarations by searching enclosing scopes (blocks or subprograms) in order of increasing size.

Consider the following skeletal C function:

```
void sub() {
  int count;
  . . .
  while (. . .) {
    int count;
    count++;
    . . .
  }
  . . .
}
```

The reference to `count` in the **`while`** loop is to that loop's local `count`. In this case, the `count` of `sub` is hidden from the code inside the **`while`** loop. In general, a declaration for a variable effectively hides any declaration of a variable with the same name in a larger enclosing scope.[7] Note that this code is legal in C and C++ but illegal in Java and C#. The designers of Java and C# believed that the reuse of names in nested blocks was too error prone to be allowed.

7. As discussed in Section 5.5.4, in C++, such hidden global variables can be accessed in the inner scope using the scope operator (::).

Although JavaScript uses static scoping for its nested functions, nonfunction blocks cannot be defined in the language.

Most functional programming languages include a construct that is related to the blocks of the imperative languages, usually named *let*. These constructs have two parts, the first of which is to bind names to values, usually specified as expressions. The second part is an expression that uses the names defined in the first part. Programs in functional languages are comprised of expressions, rather than statements. Therefore, the final part of a `let` construct is an expression, rather than a statement. In Scheme, a `let` construct is a call to the function `LET` with the following form:

- `(LET (`
- `( name1 expression1)`
- `. . .`
- `( namen expressionn))`
- expression
- `)`

The semantics of the call to `LET` is as follows: The first *n* expressions are evaluated and the values are assigned to the associated names. Then, the final expression is evaluated and the return value of `LET` is that value. This differs from a block in an imperative language in that the names are of values; they are not variables in the imperative sense. Once set, they cannot be changed. However, they are like local variables in a block in an imperative language in that their scope is local to the call to `LET`. Consider the following call to `LET`:

```
(LET (
  (top (+ a b))
  (bottom (- c d)))
  (/ top bottom)
```

`)`

This call computes and returns the value of the expression `(a + b) / (c - d)`.

In ML, the form of a **`let`** construct is as follows:

- **`let`**
- **`val`** name1 = expression1
- `...`
- **`val`** namen = expressionn
- **`in`**
- expression
- **`end`**;

Each **`val`** statement binds a name to an expression. As with Scheme, the names in the first part are like the named constants of imperative languages; once set, they cannot be changed.[8] Consider the following **`let`** construct:

8. In Chapter 15, we will see that they can be reset, but that the process actually creates a new name.

```
let
  val  top = a + b
  val bottom = c - d
in
  top / bottom
end;
```

The general form of a **`let`** construct in F# is as follows:

- **`let`** left_side = expression

The left_side of **`let`** can be a name or a tuple pattern (a sequence of names separated by commas).

The scope of a name defined with **let** inside a function definition is from the end of the defining expression to the end of the function. The scope of **let** can be limited by indenting the following code, which creates a new local scope. Although any indentation will work, the convention is that the indentation is four spaces. Consider the following code:

```
let n1 =
    let  n2 = 7
    let  n3 = n2 + 3
    n3;;
let n4 = n3 + n1;;
```

The scope of `n1` extends over all of the code. However, the scope of `n2` and `n3` ends when the indentation ends. So, the use of `n3` in the last **let** causes an error. The last line of the **let** `n1` scope is the value bound to `n1`; it could be any expression.

Chapter 15 includes more details of the let constructs in Scheme, ML, Haskell, and F#.

5.5.3 Declaration Order

In C89, as well as in some other languages, all data declarations in a function except those in nested blocks must appear at the beginning of the function. However, some languages—for example, C99, C++, Java, JavaScript, and C#—allow variable declarations to appear anywhere a statement can appear in a program unit. Declarations may create scopes that are not associated with compound statements or subprograms. For example, in C99, C++, and Java, the scope of all local variables is from their declarations to the ends of the blocks in which those declarations appear.

In the official documentation for C#, the scope of any variable declared in a block is said to be the whole block, regardless of the position of the declaration in the block, as long as it is not in a nested block. The same is true for methods. However, this is misleading, because the C# language definition requires that all variables be declared before they are used. Therefore, although the scope of a variable is said to extend from the declaration to the

top of the block or subprogram in which that declaration appears, the variable still cannot be used above its declaration.

Recall that C# does not allow the declaration of a variable in a nested block to have the same name as a variable in a nesting scope. This, together with the rule that the scope of a declaration is the whole block, makes the following nested declaration of `x` illegal:

```
{
  {int  x;  // Illegal
  ...
  }
  int  x;
}
```

Note that C# still requires that all be declared before they are used. Therefore, although the scope of a variable extends from the declaration to the top of the block or subprogram in which that declaration appears, the variable still cannot be used above its declaration.

In JavaScript, local variables can be declared anywhere in a function, but the scope of such a variable is always the entire function. If used before its declaration in the function, such a variable has the value `undefined`. The reference is not illegal.

The **`for`** statements of C++, Java, and C# allow variable definitions in their initialization expressions. In early versions of C++, the scope of such a variable was from its definition to the end of the smallest enclosing block. In the standard version, however, the scope is restricted to the **`for`** construct, as is the case with Java and C#. Consider the following skeletal method:

```
void  fun() {
   . . .
   for (int  count = 0; count < 10; count++){
     . . .
   }
   . . .
}
```

In later versions of C++, as well as in Java and C#, the scope of `count` is from the **`for`** statement to the end of its body (the right brace).

5.5.4 Global Scope

Some languages, including C, C++, PHP, JavaScript, and Python, allow a program structure that is a sequence of function definitions, in which variable definitions can appear outside the functions. Definitions outside functions in a file create global variables, which potentially can be visible to those functions.

C and C++ have both declarations and definitions of global data. Declarations specify types and other attributes but do not cause allocation of storage. Definitions specify attributes *and* cause storage allocation. For a specific global name, a C program can have any number of compatible declarations, but only a single definition.

A declaration of a variable outside function definitions specifies that the variable is defined in a different file. A global variable in C is implicitly visible in all subsequent functions in the file, except those that include a declaration of a local variable with the same name. A global variable that is defined after a function can be made visible in the function by declaring it to be external, as in the following:

```
extern int  sum;
```

In C99, definitions of global variables usually have initial values. Declarations of global variables never have initial values. If the declaration is outside function definitions, it need not include the **`extern`** qualifier.

This idea of declarations and definitions carries over to the functions of C and C++, where prototypes declare names and interfaces of functions but do not provide their code. Function definitions, on the other hand, are complete.

In C++, a global variable that is hidden by a local with the same name can be accessed using the scope operator (`::`). For example, if `x` is a global that is hidden in a function by a local named `x`, the global could be referenced as `::x`.

PHP statements can be interspersed with function definitions. Variables in

PHP are implicitly declared when they appear in statements. Any variable that is implicitly declared outside any function is a global variable; variables implicitly declared in functions are local variables. The scope of global variables extends from their declarations to the end of the program but skips over any subsequent function definitions. So, global variables are not implicitly visible in any function. Global variables can be made visible in functions in their scope in two ways: (1) If the function includes a local variable with the same name as a global, that global can be accessed through the `$GLOBALS` array, using the name of the global as a string literal subscript, and (2) if there is no local variable in the function with the same name as the global, the global can be made visible by including it in a `global` declaration statement. Consider the following example:

```
$day = "Monday";
$month = "January";
function calendar() {
  $day = "Tuesday";
  global $month;
  print "local day is $day  ";
  $gday = $GLOBALS['day'];
  print "global day is $gday <br \>";
  print "global month is $month ";
}
calendar();
```

Interpretation of this code produces the following:

```
local day is Tuesday
global day is Monday
global month is January
```

The global variables of JavaScript are very similar to those of PHP, except that there is no way to access a global variable in a function that has declared a local variable with the same name.

The visibility rules for global variables in Python are unusual. Variables are not normally declared, as in PHP. They are implicitly declared when they appear as the targets of assignment statements. A global variable can be referenced in a function, but a global variable can be assigned in a function only if it has been declared to be global in the function. Consider the following examples:

```
day = "Monday"
def tester():
print "The global day is:", day
tester()
```

The output of this script, because globals can be referenced directly in -functions, is as follows:

```
The global day is: Monday
```

The following script attempts to assign a new value to the global `day`:

```
day = "Monday"
def  tester():
  print "The global day is:", day
  day = "Tuesday"
  print "The new value of day is:", day
tester()
```

This script creates an `UnboundLocalError` error message, because the assignment to `day` in the second line of the body of the function makes `day` a local variable, which makes the reference to `day` in the first line of the body of the function an illegal forward reference to the local.

The assignment to `day` can be to the global variable if `day` is declared to be global at the beginning of the function. This prevents the assignment to `day` from creating a local variable. This is shown in the following script:

```
day = "Monday"
def tester():
  global  day
  print  "The global day is:", day
  day = "Tuesday"
  print  "The new value of day is:", day
tester()
```

The output of this script is as follows:

```
The global day is: Monday
The new value of day is: Tuesday
```

Functions can be nested in Python. Variables defined in nesting functions are accessible in a nested function through static scoping, but such variables must

be declared **`nonlocal`** in the nested function.9 An example skeletal program in Section 5.7 illustrates accesses to nonlocal variables.

9. The **`nonlocal`** reserved word was introduced in Python 3.

All names defined outside function definitions in F# are globals. Their scope extends from their definitions to the end of the file.

Declaration order and global variables are also issues in the class and member declarations in object-oriented languages. These are discussed in Chapter 12.

5.5.5 Evaluation of Static Scoping

Static scoping provides a method of nonlocal access that works well in many situations. However, it is not without its problems. First, in most cases it allows more access to both variables and subprograms than is necessary. It is simply too crude a tool for concisely specifying such restrictions. Second, and perhaps more important, is a problem related to program evolution. Software is highly dynamic—programs that are used regularly continually change. These changes often result in restructuring, thereby destroying the initial structure that restricted variable and subprogram access in a static-scoped language. To avoid the complexity of maintaining these access restrictions, developers often discard structure when it gets in the way. Thus, getting around the restrictions of static scoping can lead to program designs that bear little resemblance to the original, even in areas of the program in which changes have not been made. Designers are encouraged to use far more globals than are necessary. All subprograms can end up being nested at the same level, in the main program, using globals instead of deeper levels of nesting.10 Moreover, the final design may be awkward and contrived, and it may not reflect the underlying conceptual design. These and other defects of static scoping are discussed in detail in Clarke, Wileden, and Wolf (1980). An alternative to the use of static scoping to control access to variables and subprograms is an encapsulation construct, which is included in many newer languages. Encapsulation constructs are discussed in Chapter 11.

10. Sounds like the structure of a C program, doesn’t it?

5.5.6 Dynamic Scope

The scope of variables in APL, SNOBOL4, and the early versions of Lisp is dynamic. Perl and Common Lisp also allow variables to be declared to have dynamic scope, although the default scoping mechanism in these languages is static. **Dynamic scoping** is based on the calling sequence of subprograms, not on their spatial relationship to each other. Thus, the scope can be determined only at run time.

Consider again the function `big` from Section 5.5.1, which is reproduced here, minus the function calls:

```
function  big() {
  function  sub1() {
    var  x = 7;
  }
  function  sub2() {
    var  y = x;
    var  z = 3;
  }
  var  x = 3;
}
```

Assume that dynamic-scoping rules apply to nonlocal references. The meaning of the identifier `x` referenced in `sub2` is dynamic—it cannot be determined at compile time. It may reference the variable from either declaration of `x`, depending on the calling sequence.

One way the correct meaning of `x` can be determined during execution is to begin the search with the local declarations. This is also the way the process begins with static scoping, but that is where the similarity between the two techniques ends. When the search of local declarations fails, the declarations of the dynamic parent, or calling function, are searched. If a declaration for `x` is not found there, the search continues in that function's dynamic parent, and so forth, until a declaration for `x` is found. If none is found in any dynamic ancestor, it is a run-time error.

Consider the two different call sequences for `sub2` in the earlier example. First, `big` calls `sub1`, which calls `sub2`. In this case, the search proceeds from

the local procedure, `sub2`, to its caller, `sub1`, where a declaration for `x` is found. So, the reference to `x` in `sub2` in this case is to the `x` declared in `sub1`. Next, `sub2` is called directly from `big`. In this case, the dynamic parent of `sub2` is `big`, and the reference is to the `x` declared in `big`.

Note that if static scoping were used, in either calling sequence discussed, the reference to `x` in `sub2` would be to `big`'s `x`.

Perl's dynamic scoping is unusual—in fact, it is not exactly like that discussed in this section, although the semantics are often that of traditional dynamic scoping (see Programming Exercise 1).

5.5.7 Evaluation of Dynamic Scoping

The effect of dynamic scoping on programming is profound. When dynamic scoping is used, the correct attributes of nonlocal variables visible to a program statement cannot be determined statically. Furthermore, a reference to the name of such a variable is not always to the same variable. A statement in a subprogram that contains a reference to a nonlocal variable can refer to different nonlocal variables during different executions of the subprogam. Several kinds of programming problems follow directly from dynamic scoping.

First, during the time span beginning when a subprogram begins its execution and ending when that execution ends, the local variables of the subprogram are all visible to any other executing subprogram, regardless of its textual proximity or how execution got to the currently executing subprogram. There is no way to protect local variables from this accessibility. Subprograms are *always* executed in the environment of all previously called subprograms that have not yet completed their executions. As a result, dynamic scoping results in less reliable programs than static scoping.

A second problem with dynamic scoping is the inability to type check references to nonlocals statically. This problem results from the inability to

statically find the declaration for a variable referenced as a nonlocal.

Dynamic scoping also makes programs much more difficult to read, because the calling sequence of subprograms must be known to determine the meaning of references to nonlocal variables. This task can be virtually impossible for a human reader.

Finally, accesses to nonlocal variables in dynamic-scoped languages take far longer than accesses to nonlocals when static scoping is used. The reason for this is explained in Chapter 10.

On the other hand, dynamic scoping is not without merit. In many cases, the parameters passed from one subprogram to another are variables that are defined in the caller. None of these needs to be passed in a dynamically scoped language, because they are implicitly visible in the called subprogram.

It is not difficult to understand why dynamic scoping is not as widely used as static scoping. Programs in static-scoped languages are easier to read, are more reliable, and execute faster than equivalent programs in dynamic-scoped languages. It was precisely for these reasons that dynamic scoping was replaced by static scoping in most current dialects of Lisp. Implementation methods for both static and dynamic scoping are discussed in Chapter 10.

5.6 Scope and Lifetime

Sometimes the scope and lifetime of a variable appear to be related. For example, consider a variable that is declared in a Java method that contains no method calls. The scope of such a variable is from its declaration to the end of the method. The lifetime of that variable is the period of time beginning when the method is entered and ending when execution of the method terminates. Although the scope and lifetime of the variable are clearly not the same, because static scope is a textual, or spatial, concept whereas lifetime is a temporal concept, they at least appear to be related in this case.

This apparent relationship between scope and lifetime does not hold in other situations. In C and C++, for example, a variable that is declared in a function using the specifier **`static`** is statically bound to the scope of that function and is also statically bound to storage. So, its scope is static and local to the function, but its lifetime extends over the entire execution of the program of which it is a part.

Scope and lifetime are also unrelated when subprogram calls are involved. Consider the following C++ functions:

```
void printheader() {
  . . .
 } /* end of printheader */
void compute() {
  int sum;
  . . .
  printheader();
 } /* end of compute */
```

The scope of the variable `sum` is completely contained within the `compute` function. It does not extend to the body of the function `printheader`, although `printheader` executes in the midst of the execution of `compute`. However, the lifetime of `sum` extends over the time during which `printheader` executes. Whatever storage location `sum` is bound to before the call to `printheader`, that binding will continue during and after the execution of `printheader`.

5.7 Referencing Environments

The **referencing environment** of a statement is the collection of all variables that are visible in the statement. The referencing environment of a statement in a static-scoped language is the variables declared in its local scope plus the collection of all variables of its ancestor scopes that are visible. In such a language, the referencing environment of a statement is needed while that statement is being compiled, so code and data structures can be created to allow references to variables from other scopes during run time. Techniques for implementing references to nonlocal variables in both static- and dynamic-scoped languages are discussed in Chapter 10.

In Python, scopes can be created by function definitions. The referencing environment of a statement includes the local variables, plus all of the variables declared in the functions in which the statement is nested (excluding variables in nonlocal scopes that are hidden by declarations in nearer functions). Each function definition creates a new scope and thus a new environment. Consider the following Python skeletal program:

```
g = 3; # A global
def sub1():
    a = 5; # Creates a local
    b = 7; # Creates another local
    . . . <------------------------------ 1
  def  sub2():
  global g;  # Global g is now assignable here
    c = 9;  # Creates a new local
    . . . <------------------------------ 2
    def  sub3():
      nonlocal  c:  # Makes nonlocal c visible here
      g = 11;  # Creates a new local
      . . . <------------------------------ 3
```

The referencing environments of the indicated program points are as follows:

Point	*Referencing Environment*
1	local `a` and `b` (of `sub1`), global `g` for reference, but not for assignment
2	local `c` (of `sub2`), global `g` for both reference and for assignment
3	nonlocal `c` (of `sub2`), local `g` (of `sub3`)

Now consider the variable declarations of this skeletal program. First, note that, although the scope of `sub1` is at a higher level (it is less deeply nested) than `sub3`, the scope of `sub1` is not a static ancestor of `sub3`, so `sub3` does not have access to the variables declared in `sub1`. There is a good reason for this. The variables declared in `sub1` are stack dynamic, so they are not bound to storage if `sub1` is not in execution. Because `sub3` can be in execution when `sub1` is not, it cannot be allowed to access variables in `sub1`, which would not necessarily be bound to storage during the execution of `sub3`.

A subprogram is **active** if its execution has begun but has not yet terminated. The referencing environment of a statement in a dynamically scoped language is the locally declared variables, plus the variables of all other - subprograms that are currently active. Once again, some variables in active subprograms can be hidden from the referencing environment. Recent subprogram activations can have declarations for variables that hide variables with the same names in previous subprogram activations.

Consider the following example program. Assume that the only function calls are the following: `main` calls `sub2`, which calls `sub1`.

```
void sub1() {
  int a, b;
  . . . <------------ 1
}  /* end of sub1 */
void sub2() {
  int b, c;
  . . . . <------------ 2
  sub1();
}  /* end of sub2 */
void main() {
  int c, d;
```

```
  . . . <------------ 3
  sub2();
}  /* end of main */
```

The referencing environments of the indicated program points are as follows:

Point	*Referencing Environment*
1	`a` and `b` of `sub1`, `c` of `sub2`, `d` of `main`, (`c` of `main` and `b` of `sub2` are hidden)
2	`b` and `c` of `sub2`, `d` of `main`, (`c` of `main` is hidden)
3	`c` and `d` of `main`

5.8 Named Constants

A **named constant** is a variable that is bound to a value only once. Named constants are useful as aids to readability and program reliability. Readability can be improved, for example, using the name `pi` instead of the constant `3.14159265`.

Another important use of named constants is to parameterize a program. For example, consider a program that processes a fixed number of data values, say 100. Such a program usually uses the constant `100` in a number of locations for declaring array subscript ranges and for `loop` control limits. Consider the following skeletal Java program segment:

```
void example() {
  int[] intList = new int[100];
  String[] strList =  new  String[100];
  . . .
  for  (index = 0; index < 100; index++) {
    . . .
  }
  . . .
  for  (index = 0; index < 100; index++) {
    . . .
  }
  . . .
  average = sum / 100;
  . . .
}
```

When this program must be modified to deal with a different number of data values, all occurrences of `100` must be found and changed. On a large program, this can be tedious and error prone. An easier and more reliable method is to use a named constant as a program parameter, as follows:

```
void example() {
  final int  len = 100;
  int[] intList =  new int[len];
  String[] strList =  new  String[len];
  . . .
  for (index = 0; index < len; index++) {
```

```
    . . .
  }
  . . .
  for (index = 0; index < len; index++) {
    . . .
  }
  . . .
  average = sum / len;
  . . .
}
```

Now, when the length must be changed, only one line must be changed (the variable `len`), regardless of the number of times it is used in the program. This is another example of the benefits of abstraction. The name `len` is an abstraction for the number of elements in some arrays and the number of iterations in some loops. This illustrates how named constants can aid modifiability.

C++ allows dynamic binding of values to named constants. This allows expressions containing variables to be assigned to constants in the declarations. For example, the C++ statement

```
const int  result = 2 * width + 1;
```

declares `result` to be an integer type named constant whose value is set to the value of the expression `2 * width + 1`, where the value of the variable `width` must be visible when `result` is allocated and bound to its value.

Java also allows dynamic binding of values to named constants. In Java, named constants are defined with the **`final`** reserved word (as in the earlier example). The initial value can be given in the declaration statement or in a subsequent assignment statement. The assigned value can be specified with any expression.

C# has two kinds of named constants: those defined with **`const`** and those defined with **`readonly`**. The **`const`** named constants, which are implicitly **`static`**, are statically bound to values; that is, they are bound to values at compile time, which means those values can be specified only with literals or other **`const`** members. The **`readonly`** named constants, which are dynamically bound to values, can be assigned in the declaration or with a

static constructor.11 So, if a program needs a constant-valued object whose value is the same on every use of the program, a **`const`** constant is used. However, if a program needs a constant-valued object whose value is determined only when the object is created and can be different for different executions of the program, then a **`readonly`** constant is used.

11. Static constructors in C# run at some indeterminate time before the class is instantiated.

The discussion of binding values to named constants naturally leads to the topic of initialization, because binding a value to a named constant is the same process, except it is permanent.

In many instances, it is convenient for variables to have values before the code of the program or subprogram in which they are declared begins executing. The binding of a variable to a value at the time it is bound to storage is called **initialization**. If the variable is statically bound to storage, binding and initialization occur before run time. In these cases, the initial value must be specified as a literal or an expression whose only nonliteral operands are named constants that have already been defined. If the storage binding is dynamic, initialization is also dynamic and the initial values can be any expression.

In most languages, initialization is specified on the declaration that creates the variable. For example, in C++, we could have

```
int sum = 0;
int* ptrSum = &sum;
char name[] = "George Washington Carver";
```

SUMMARY

Case sensitivity and the use of underscores are the design issues for names.

Variables can be characterized by the sextuple of attributes: name, address, value, type, lifetime, and scope.

Aliases are two or more variables bound to the same storage address. They are regarded as detrimental to reliability but are difficult to eliminate entirely from a language.

Binding is the association of attributes with program entities. Knowledge of the binding times of attributes to entities is essential to understanding the semantics of programming languages. Binding can be static or dynamic. - Declarations, either explicit or implicit, provide a means of specifying the static binding of variables to types. In general, dynamic binding allows greater flexibility but at the expense of readability, efficiency, and reliability.

Scalar variables can be separated into four categories by considering their lifetimes: static, stack dynamic, explicit heap dynamic, and implicit heap dynamic.

Static scoping is a central feature of ALGOL 60 and some of its descendants. It provides a simple, reliable, and efficient method of allowing visibility of nonlocal variables in subprograms. Dynamic scoping provides more flexibility than static scoping but, again, at the expense of readability, reliability, and efficiency.

Most functional languages allow the user to create local scopes with `let` constructs, which limit the scope of their defined names.

The referencing environment of a statement is the collection of all of the variables that are visible to that statement.

Named constants are simply variables that are bound to values only once.

REVIEW QUESTIONS

1. What are the design issues for names?
2. What is the potential danger of case-sensitive names?
3. What is an alias?
4. Which category of C++ reference variables always produces aliases?
5. What is the *l*-value of a variable? What is the *r*-value?
6. Define *binding* and *binding time*.
7. After language design and implementation, what are the four times bindings can take place in a program?
8. Define *static binding* and *dynamic binding*.
9. What are the advantages and disadvantages of implicit declarations?
10. What are the advantages and disadvantages of dynamic type binding?
11. Define *static*, *stack-dynamic*, *explicit heap-dynamic*, and *implicit heap-dynamic variables*. What are their advantages and disadvantages?
12. Define *lifetime, scope, static scope,* and *dynamic scope*.
13. How is a reference to a nonlocal variable in a static-scoped program connected to its definition?
14. What is the general problem with static scoping?
15. What is the referencing environment of a statement?
16. What is a static ancestor of a subprogram? What is a dynamic ancestor of a subprogram?

17. What is a block?

18. What is the purpose of the `let` constructs in functional languages?

19. What is the difference between the names defined in an ML `let` construct from the variables declared in a C block?

20. Describe the encapsulation of an F# `let` inside a function and outside all functions.

21. What are the advantages and disadvantages of dynamic scoping?

22. What are the advantages of named constants?

PROBLEM SET

1. Which of the following identifier forms is most readable? Support your decision.

   ```
   SumOfSales
   sum_of_sales
   SUMOFSALES
   ```

2. Some programming languages are typeless. What are the obvious advantages and disadvantages of having no types in a language?

3. Write a simple assignment statement with one arithmetic operator in some language you know. For each component of the statement, list the various bindings that are required to determine the semantics when the statement is executed. For each binding, indicate the binding time used for the language.

4. Dynamic type binding is closely related to implicit heap-dynamic variables. Explain this relationship.

5. Describe a situation when a history-sensitive variable in a subprogram is useful.

6. Consider the following JavaScript skeletal program:

   ```
   // The main program
   var  x;
   function  sub1() {
     var  x;
     function  sub2() {
       . . .
     }
   }
   function  sub3() {
     . . .
   }
   ```

   Assume that the execution of this program is in the following unit order:

- `main` calls `sub1`
- `sub1` calls `sub2`
- `sub2` calls `sub3`

1. Assuming static scoping, in the following, which declaration of `x` is the correct one for a reference to `x`?
    1. `sub1`
    2. `sub2`
    3. `sub3`
2. Repeat part a, but assume dynamic scoping.

7. Assume the following JavaScript program was interpreted using static-scoping rules. What value of `x` is displayed in function `sub1`? Under dynamic-scoping rules, what value of `x` is displayed in function `sub1`?

```
var x;
function  sub1() {
  document.write("x = " + x + "");
}
function  sub2() {
   var x;
   x = 10;
   sub1();
}
x = 5;
sub2();
```

8. Consider the following JavaScript program:

```
var  x, y, z;
function  sub1() {
  var  a, y, z;
  function sub2() {
    var  a, b, z;
    . . .
  }
```

```
  . . .
}
function  sub3() {
  var  a, x, w;
  . . .
}
```

List all the variables, along with the program units where they are declared, that are visible in the bodies of `sub1`, `sub2`, and `sub3`, assuming static scoping is used.

9. Consider the following Python program:

```
x = 1;
y = 3;
z = 5;
def sub1():
  a = 7;
  y = 9;
  z = 11;
  . . .
def sub2():
  global  x;
  a = 13;
  x = 15;
  w = 17;
  . . .
  def sub3():
    nonlocal  a;
    a = 19;
    b = 21;
    z = 23;
    . . .
. . .
```

List all the variables, along with the program units where they are declared, that are visible in the bodies of `sub1`, `sub2`, and `sub3`, assuming static scoping is used.

10. Consider the following C program:

```
void fun(void) {
  int a, b, c; /* definition 1 */
  . . .
  while (. . .) {
```

```
    int b, c, d; /*definition 2 */
    . . . <-------------  1
    while (. . .) {
    int c, d, e; /* definition 3 */
    . . . <-------------  2
    }
   . . . <--------------  3
   }
  . . . <----------------  4
}
```

For each of the four marked points in this function, list each visible - variable, along with the number of the definition statement that defines it.

11. Consider the following skeletal C program:

```
void fun1(void);  /* prototype */
void fun2(void);  /* prototype */
void fun3(void);  /* prototype */
void main() {
  int a, b, c;
  . . .
 }
void  fun1(void) {
  int  b, c, d;
  . . .
 }
void  fun2(void) {
  int  c, d, e;
  . . .
 }
void  fun3(void) {
  int  d, e, f;
  . . .
 }
```

Given the following calling sequences and assuming that dynamic scoping is used, what variables are visible during execution of the last function called? Include with each visible variable the name of the function in which it was defined.

1. `main` calls `fun1`; `fun1` calls `fun2`; `fun2` calls `fun3`.

2. `main` calls `fun1`; `fun1` calls `fun3`.

3. `main` calls `fun2`; `fun2` calls `fun3`; `fun3` calls `fun1`.

4. `main` calls `fun3`; `fun3` calls `fun1`.

5. `main` calls `fun1`; `fun1` calls `fun3`; `fun3` calls `fun2`.

6. `main` calls `fun3`; `fun3` calls `fun2`; `fun2` calls `fun1`.

12. Consider the following program, written in JavaScript-like syntax:

```
// main program
var  x, y, z;
function  sub1() {
var  a, y, z;
. . .
}
function  sub2() {
  var  a, b, z;
  . . .
}
function  sub3() {
  var  a, x, w;
  . . .
}
```

Given the following calling sequences and assuming that dynamic scoping is used, what variables are visible during execution of the last subprogram activated? Include with each visible variable the name of the unit where it is declared.

1. `main` calls `sub1`; `sub1` calls `sub2`; `sub2` calls `sub3`.

2. `main` calls `sub1`; `sub1` calls `sub3`.

3. `main` calls `sub2`; `sub2` calls `sub3`; `sub3` calls `sub1`.

4. `main` calls `sub3`; `sub3` calls `sub1`.

5. `main` calls `sub1`; `sub1` calls `sub3`; `sub3` calls `sub2`.

6. `main` calls `sub3`; `sub3` calls `sub2`; `sub2` calls `sub1`.

PROGRAMMING EXERCISES

1. Perl allows both static and a kind of dynamic scoping. Write a Perl program that uses both and clearly shows the difference in effect of the two. Explain clearly the difference between the dynamic scoping described in this chapter and that implemented in Perl.

2. Write a Common Lisp program that clearly shows the difference between static and dynamic scoping.

3. Write a JavaScript script that has subprograms nested three deep and in which each nested subprogram references variables defined in all of its enclosing subprograms.

4. Repeat Programming Exercise 3 with Python.

5. Write a C99 function that includes the following sequence of statements:

```
x = 21;
int x;
x = 42;
```

   Run the program and explain the results. Rewrite the same code in C++ and Java and compare the results.

6. Write test programs in C++, Java, and C# to determine the scope of a variable declared in a **`for`** statement. Specifically, the code must determine whether such a variable is visible after the body of the **`for`** statement.

7. Write three functions in C or C++: one that declares a large array statically, one that declares the same large array on the stack, and one that creates the same large array from the heap. Call each of the subprograms a large number of times (at least 100,000) and output the time required by each. Explain the results.

6 Data Types

This chapter first introduces the concept of a data type and the characteristics of the common primitive data types. Then, the designs of enumeration and subrange types are discussed. Next, the details of structured data types—

specifically arrays, associative arrays, records, tuples, lists, and unions—are investigated. This section is followed by an in-depth look at pointers and references. The last category of types discussed are the optional types.

For each of the various categories of data types, the design issues are stated and the design choices made by the designers of some common languages are described. These designs are then evaluated.

The next three sections provide a thorough investigation of type checking, strong typing, and type equivalence rules. The last section of the chapter briefly introduces the fundamentals of the theory of data types.

Implementation methods for data types sometimes have a significant impact on their design. Therefore, implementation of the various data types is another important part of this chapter, especially arrays.

6.1 Introduction

A **data type** defines a collection of data values and a set of predefined operations on those values. Computer programs produce results by manipulating data. An important factor in determining the ease with which they can perform this task is how well the data types available in the language being used match the objects in the real world of the problem being addressed. Therefore, it is crucial that a language supports an appropriate collection of data types and structures.

The contemporary concepts of data typing have evolved over the last 60 years. In the earliest languages, all problem space data structures had to be modeled with only a few basic language-supported data structures. For example, in pre-90 Fortrans, linked lists and binary trees were implemented with arrays.

The data structures of COBOL took the first step away from the Fortran I model by allowing programmers to specify the accuracy of decimal data values, and also by providing a structured data type for records of information. PL/I extended the capability of accuracy specification to integer and floating-point types. The designers of PL/I included many data types, with the intent of supporting a large range of applications. A better approach, introduced in ALGOL 68, is to provide a few basic types and a few flexible structure-defining operators that allow a programmer to design a data structure for each need. Clearly, this was one of the most important advances in the evolution of data type design. User-defined types also provide improved readability through the use of meaningful names for types. They allow type checking of the variables of a special category of use, which would otherwise not be possible. User-defined types also aid modifiability: A programmer can change the type of a category of variables in a program by changing a type definition statement only.

Taking the concept of a user-defined type a step further, we arrive at abstract data types, which are supported by most programming languages designed since the mid-1980s. The fundamental idea of an abstract data type is that the

interface of a type, which is visible to the user, is separated from the representation and set of operations on values of that type, which are hidden from the user. All of the types provided by a high-level programming language are abstract data types. User-defined abstract data types are discussed in detail in Chapter 11.

There are a number of uses of the type system of a programming language. The most practical of these is error detection. The process and value of type checking, which is directed by the type system of the language, are discussed in Section 6.12. A second use of a type system is the assistance it provides for program modularization. This results from the cross-module type checking that ensures the consistency of the interfaces among modules. Another use of a type system is documentation. The type declarations in a program document information about its data, which provides clues about the program's behavior.

The type system of a programming language defines how a type is associated with each expression in the language and includes its rules for type equivalence and type compatibility. Certainly, one of the most important parts of understanding the semantics of a programming language is understanding its type system.

The two most common structured (nonscalar) data types in the imperative languages are arrays and records, although the popularity of associative arrays has increased significantly in recent years. Lists have been a central part of functional programming languages since the first such language appeared in 1959 (Lisp). Over the last decade, the increasing popularity of functional programming has led to lists being added to primarily imperative languages, such as Python and C#.

The structured data types are defined with type operators, or constructors, which are used to form type expressions. For example, C uses brackets and asterisks as type operators to specify arrays and pointers.

It is convenient, both logically and concretely, to think of variables in terms of descriptors. A **descriptor** is the collection of the attributes of a variable. In an implementation, a descriptor is an area of memory that stores the attributes of a variable. If the attributes are all static, descriptors are required only at

compile time. These descriptors are built by the compiler, usually as a part of the symbol table, and are used during compilation. For dynamic attributes, however, part or all of the descriptor must be maintained during execution. In this case, the descriptor is used by the run-time system. In all cases, descriptors are used for type checking and building the code for the allocation and deallocation operations.

Care must be taken when using the term *variable*. One who uses only traditional imperative languages may think of identifiers as variables, but that can lead to confusion when considering data types. Identifiers do not have data types in some programming languages. It is wise to remember that identifiers are just one of the attributes of a variable.

The word *object* is often associated with the value of a variable and the space it occupies. In this book, however, we reserve *object* exclusively for instances of user-defined and language-defined abstract data types, rather than for the values of all program variables of predefined types. Objects are discussed in detail in Chapters 11 and 12.

In the following sections, many common data types are discussed. For most, design issues particular to the type are stated. For all, one or more example designs are described. One design issue is fundamental to all data types: What operations are provided for variables of the type, and how are they specified?

6.2 Primitive Data Types

Data types that are not defined in terms of other types are called **primitive data types**. Nearly all programming languages provide a set of primitive data types. Some of the primitive types are merely reflections of the hardware—for example, most integer types. Others require only a little nonhardware support for their implementation.

To specify the structured types, the primitive data types of a language are used, along with one or more type constructors.

6.2.1 Numeric Types

Some early programming languages only had numeric primitive types. Numeric types still play a central role among the collections of types supported by contemporary languages.

6.2.1.1 Integer

The most common primitive numeric data type is `integer`. The hardware of many computers supports several sizes of integers. These sizes of integers, and often a few others, are supported by some programming languages. For example, Java includes four signed integer sizes: `byte`, `short`, `int`, and `long`. Some languages, for example, C++ and C#, include unsigned integer types, which are types for integer values without signs. Unsigned types are often used for binary data.

A signed integer value is represented in a computer by a string of bits, with one of the bits (typically the leftmost) representing the sign. Most integer types are supported directly by the hardware. One example of an integer type that is not supported directly by the hardware is the long integer type of Python (F# also provides such integers). Values of this type can have

unlimited length. Long integer values can be specified as literals, as in the following example:

```
243725839182756281923L
```

Integer arithmetic operations in Python that produce values too large to be represented with **`int`** type store them as long integer type values.

A negative integer could be stored in sign-magnitude notation, in which the sign bit is set to indicate negative and the remainder of the bit string represents the absolute value of the number. Sign-magnitude notation, however, does not lend itself to computer arithmetic. Most computers now use a notation called **twos complement** to store negative integers, which is convenient for addition and subtraction. In twos-complement notation, the representation of a negative integer is formed by taking the logical complement of the positive version of the number and adding one. Ones-complement notation is still used by some computers. In ones-complement notation, the negative of an integer is stored as the logical complement of its absolute value. Ones-complement notation has the disadvantage that it has two representations of zero. See any book on assembly language programming for details of integer representations.

6.2.1.2 Floating-Point

Floating-point data types model real numbers, but the representations are only approximations for many real values. For example, neither of the fundamental numbers π or *e* (the base for the natural logarithms) can be correctly represented in floating-point notation. Of course, neither of these numbers can be precisely represented in any finite amount of computer memory. On most computers, floating-point numbers are stored in binary, which exacerbates the problem. For example, even the value 0.1 in decimal cannot be represented by a finite number of binary digits.[1] Another problem with floating-point types is the loss of accuracy through arithmetic operations. For more information on the problems of floating-point notation, see any book on numerical analysis.

1. 0.1 in decimal is 0.0001100110011 . . . in binary.

Floating-point values are represented as fractions and exponents, a form that is borrowed from scientific notation. Older computers used a variety of different representations for floating-point values. However, most newer machines use the IEEE Floating-Point Standard 754 format. Language implementors use whatever representation is supported by the hardware. Most languages include two floating-point types, often called **float** and **double**. The float type is the standard size, usually stored in four bytes of memory. The double type is provided for situations where larger fractional parts and/or a larger range of exponents is needed. Double-precision variables usually occupy twice as much storage as float variables and provide at least twice the number of bits of fraction.

The collection of values that can be represented by a floating-point type is defined in terms of precision and range. **Precision** is the accuracy of the fractional part of a value, measured as the number of bits. **Range** is a combination of the range of fractions and, more important, the range of exponents.

Figure 6.1 shows the IEEE Floating-Point Standard 754 format for single- and double-precision representation (IEEE, 1985). Details of the IEEE formats can be found in Tanenbaum (2005).

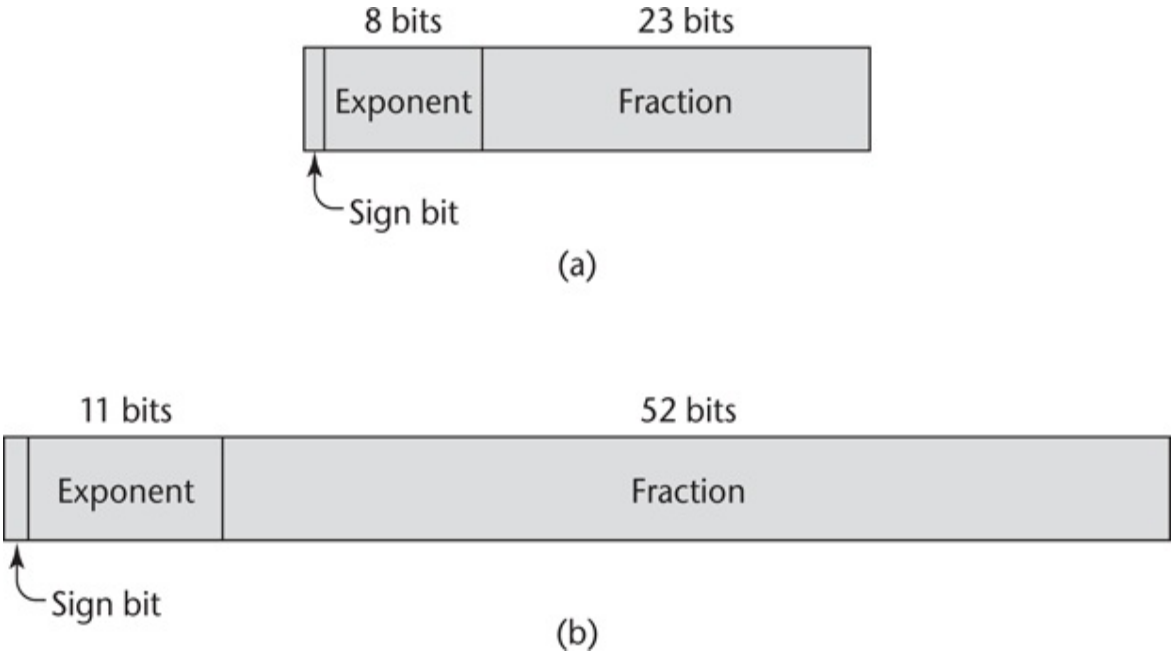

Figure 6.1 IEEE floating-point formats: (a) single precision, (b) double precision

Figure 6.1 Full Alternative Text

6.2.1.3 Complex

Some programming languages support a complex data type—for example, Fortran and Python. Complex values are represented as ordered pairs of floating-point values. In Python, the imaginary part of a complex literal is specified by following it with a `j` or `J`—for example,

```
(7 + 3j)
```

Languages that support a complex type include operations for arithmetic on complex values.

6.2.1.4 Decimal

Most larger computers that are designed to support business systems applications have hardware support for **decimal** data types. Decimal data types store a fixed number of decimal digits, with the implied decimal point at a fixed position in the value. These are the primary data types for business data processing and are therefore essential to COBOL. C# and F# also have decimal data types.

Decimal types have the advantage of being able to precisely store decimal values, at least those within a restricted range, which cannot be done with -floating-point. For example, the number 0.1 (in decimal) can be exactly represented in a decimal type, but not in a floating-point type, as is noted in

Section 6.2.1.2. The disadvantages of decimal types are that the range of values is restricted because no exponents are allowed, and their representation in memory is mildly wasteful, for reasons discussed in the following paragraph.

Decimal types are stored very much like character strings, using binary codes for the decimal digits. These representations are called **binary coded decimal (BCD)**. In some cases, they are stored one digit per byte, but in others, they are packed two digits per byte. Either way, they take more storage than binary representations. It takes at least four bits to code a decimal digit. Therefore, to store a six-digit coded decimal number requires 24 bits of memory. However, it takes only 20 bits to store the same number in binary.2 The operations on decimal values are done in hardware on machines that have such capabilities; otherwise, they are simulated in software.

2. Of course, unless a program needs to maintain a large number of large decimal values, the difference is insignificant.

6.2.2 Boolean Types

Boolean types are perhaps the simplest of all types. Their range of values has only two elements: one for true and one for false. They were introduced in ALGOL 60 and have been included in most general-purpose languages designed since 1960. One popular exception is C89, in which numeric expressions are used as conditionals. In such expressions, all operands with nonzero values are considered true, and zero is considered false. Although C99 and C++ have a Boolean type, they also allow numeric expressions to be used as if they were Boolean. This is not the case in the subsequent languages, Java and C#.

Boolean types are often used to represent switches or flags in programs. Although other types, such as integers, can be used for these purposes, the use of Boolean types is more readable.

A Boolean value could be represented by a single bit, but because a single bit of memory cannot be accessed efficiently on many machines, they are often

stored in the smallest efficiently addressable cell of memory, typically a byte.

6.2.3 Character Types

Character data are stored in computers as numeric codings. Traditionally, the most commonly used coding was the 8-bit code ASCII (American Standard Code for Information Interchange), which uses the values 0 to 127 to code 128 different characters. ISO 8859-1 is another 8-bit character code, but it allows 256 different characters.

Because of the globalization of business and the need for computers to communicate with other computers around the world, the ASCII character set became inadequate. In response, in 1991, the Unicode Consortium published the UCS-2 standard, a 16-bit character set. This character code is often called Unicode. Unicode includes the characters from most of the world's natural languages. For example, Unicode includes the Cyrillic alphabet, as used in Serbia, and the Thai digits. The first 128 characters of Unicode are identical to those of ASCII. Java was the first widely used language to use the Unicode character set. Since then, it has found its way into JavaScript, Python, Perl, C#, F#, and Swift.

After 1991, the Unicode Consortium, in cooperation with the International Standards Organization (ISO), developed a 4-byte character code named UCS-4, or UTF-32, which is described in the ISO/IEC 10646 Standard, published in 2000.

To provide the means of processing codings of single characters, most programming languages include a primitive type for them. However, Python supports single characters only as character strings of length 1.

6.3 Character String Types

A **character string type** is one in which the values consist of sequences of characters. Character string constants are used to label output, and the input and output of all kinds of data are often done in terms of strings. Of course, character strings also are an essential type for all programs that do character manipulation.

6.3.1 Design Issues

The two most important design issues that are specific to character string types are the following:

- Should strings be a special kind of character array or a primitive type?
- Should strings have static or dynamic length?

6.3.2 Strings and Their Operations

The most common string operations are assignment, catenation, substring reference, comparison, and pattern matching.

A **substring reference** is a reference to a substring of a given string. Substring references are discussed in the more general context of arrays, where the substring references are called **slices**.

In general, both assignment and comparison operations on character strings are complicated by the possibility of string operands of different lengths. For example, what happens when a longer string is assigned to a shorter string, or vice versa? Usually, simple and sensible choices are made for these situations, although programmers often have trouble remembering them.

In some languages, pattern matching is supported directly in the language. In others, it is provided by a function or class library.

If strings are not defined as a primitive type, string data is usually stored in arrays of single characters and referenced as such in the language. This is the approach taken by C and C++, which use **`char`** arrays to store character strings. These languages provide a collection of string operations through standard libraries. Many users of strings and many of the library functions use the convention that character strings are terminated with a special character, null, which is represented with zero. This is an alternative to maintaining the length of string variables. The library operations simply carry out their operations until the null character appears in the string being operated on. Library functions that produce strings often supply the null character. The character string literals that are built by the compiler also have the null character. For example, consider the following declaration:

```
char str[] = "apples";
```

In this example, `str` represents an array of **`char`** elements, specifically `apples0`, where `0` is the null character.

Some of the most commonly used library functions for character strings in C and C++ are `strcpy`, which moves strings; `strcat`, which catenates one given string onto another; `strcmp`, which lexicographically compares (by the order of their character codes) two given strings; and `strlen`, which returns the number of characters, not counting the null character, in the given string. The parameters and return values for most of the string manipulation functions are **`char`** pointers that point to arrays of **`char`**. Parameters can also be string literals.

The string manipulation functions of the C standard library, which are also available in C++, are inherently unsafe and have led to numerous programming errors. The problem is that the functions in this library that move string data do not guard against overflowing the destination. For example, consider the following call to `strcpy`:

```
strcpy(dest, src);
```

If the length of `dest` is 20 and the length of `src` is 50, `strcpy` will write over the 30 bytes that follow `dest`. The point is that `strcpy` does not know the length of `dest`, so it cannot ensure that the memory following it will not be overwritten. The same problem can occur with several of the other functions in the C string library. In addition to C-style strings, C++ also supports strings through its standard class library, which is also similar to that of Java. Because of the insecurities of the C string library, C++ programmers should use the `string` class from the standard library, rather than **`char`** arrays and the C string library.

In Java, strings are supported by the `String` class, whose values are constant strings, and the `StringBuffer` class, whose values are changeable and are more like arrays of single characters. These values are specified with methods of the `StringBuffer` class. C# and Ruby include string classes that are similar to those of Java.

Python includes strings as a primitive type and has operations for substring reference, catenation, indexing to access individual characters, as well as methods for searching and replacement. There is also an operation for character membership in a string. So, even though Python's strings are primitive types, for character and substring references, they act very much like arrays of characters. However, Python strings are immutable, similar to the `String` class objects of Java.

In F#, strings are a class. Individual characters, which are represented in Unicode UTF-16, can be accessed, but not changed. Strings can be catenated with the `+` operator. In ML, string is a primitive immutable type. It uses `^` for its catenation operator and includes functions for substring referencing and getting the size of a string.

In Swift, the `String` class supports its character strings. `String` objects can be either constants or variables. The binary `+` operator catenates `String` variables. The `append` method is used to add a `Character` object to a `String` object. The `characters` method of `String` is used to examine individual characters of a `String` object.

history note

SNOBOL 4 was the first widely known language to support pattern matching.

Perl, JavaScript, Ruby, and PHP include built-in pattern-matching operations. In these languages, the pattern-matching expressions are somewhat loosely based on mathematical regular expressions. In fact, they are often called **regular expressions**. They evolved from the early UNIX line editor, `ed`, to become part of the UNIX shell languages. Eventually, they grew to their current complex form. There is at least one complete book on this kind of -pattern-matching expressions (Friedl, 2006). In this section, we provide a brief look at the style of these expressions through two relatively simple examples.

Consider the following pattern expression:

```
/[A-Za-z][A-Za-z\d]+/
```

This pattern matches (or describes) the typical name form in programming languages. The brackets enclose character classes. The first character class specifies all letters; the second specifies all letters and digits (a digit is specified with the abbreviation `\d`). If only the second character class were included, we could not prevent a name from beginning with a digit. The plus operator following the second category specifies that there must be one or more of what is in the category. So, the whole pattern matches strings that begin with a letter, followed by one or more letters or digits.

Next, consider the following pattern expression:

```
/\d+\.?\d*|\.\d+/
```

This pattern matches numeric literals. The `\.` specifies a literal decimal point.3 The question mark quantifies what it follows to have zero or one appearance. The vertical bar (`|`) separates two alternatives in the whole pattern. The first alternative matches strings of one or more digits, possibly followed by a decimal point, followed by zero or more digits; the second

alternative matches strings that begin with a decimal point, followed by one or more digits.

3. The period must be “escaped” with the backslash because period has special meaning in a regular expression.

Pattern-matching capabilities using regular expressions are included in the class libraries of C++, Java, Python, C#, and F#.

6.3.3 String Length Options

There are several design choices regarding the length of string values. First, the length can be static and set when the string is created. Such a string is called a **static length string**. This is the choice for the strings of Python, the immutable objects of Java’s `String` class, as well as similar classes in the C++ standard class library, Ruby’s built-in `String` class, and the .NET class library available to C# and F#.

The second option is to allow strings to have varying length up to a declared and fixed maximum set by the variable’s definition, as exemplified by the strings in C and the C-style strings of C++. These are called **limited dynamic length strings**. Such string variables can store any number of characters between zero and the maximum. Recall that strings in C use a special character to indicate the end of the string’s characters, rather than maintaining the string length.

The third option is to allow strings to have varying length with no maximum, as in JavaScript, Perl, and the standard C++ library. These are called **dynamic length strings**. This option requires the overhead of dynamic storage allocation and deallocation but provides maximum flexibility.

6.3.4 Evaluation

String types are important to the writability of a language. Dealing with strings as arrays can be more cumbersome than dealing with a primitive

string type. For example, consider a language that treats strings as arrays of characters and does not have a predefined function that does what `strcpy` in C does. Then, a simple assignment of one string to another would require a loop. The addition of strings as a primitive type to a language is not costly in terms of either language or compiler complexity. Therefore, it is difficult to justify the omission of primitive string types in some contemporary languages. Of course, providing strings through a standard library is nearly as convenient as having them as a primitive type.

String operations such as simple pattern matching and catenation are essential and should be included for string type values. Although dynamic length strings are obviously the most flexible, the overhead of their implementation must be weighed against that additional flexibility.

6.3.5 Implementation of Character String Types

Character string types could be supported directly in hardware; but in most cases, software is used to implement string storage, retrieval, and manipulation. When character string types are represented as character arrays, the language often supplies few operations.

A descriptor for a static character string type, which is required only during compilation, has three fields. The first field of every descriptor is the name of the type. In the case of static character strings, the second field is the type's length (in characters). The third field is the address of the first character. This descriptor is shown in Figure 6.2. Limited dynamic strings require a run-time descriptor to store the fixed maximum length, the current length, and the address, as shown in Figure 6.3. Dynamic length strings require a simpler run-time descriptor because only the current length and the address need to be stored. Although we depict descriptors as independent blocks of storage, in most cases, they are stored in the symbol table.

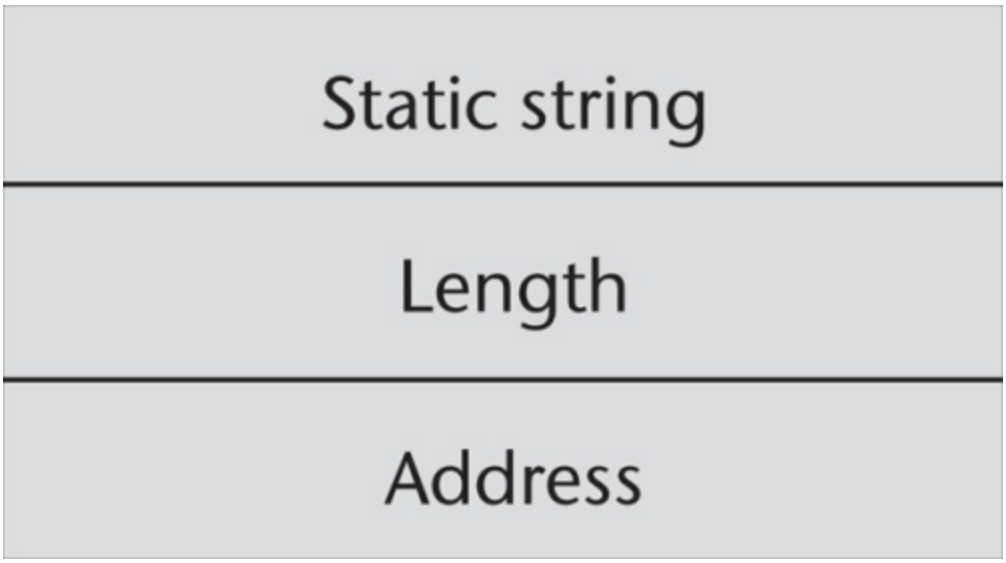

Figure 6.2 Compile-time descriptor for static strings

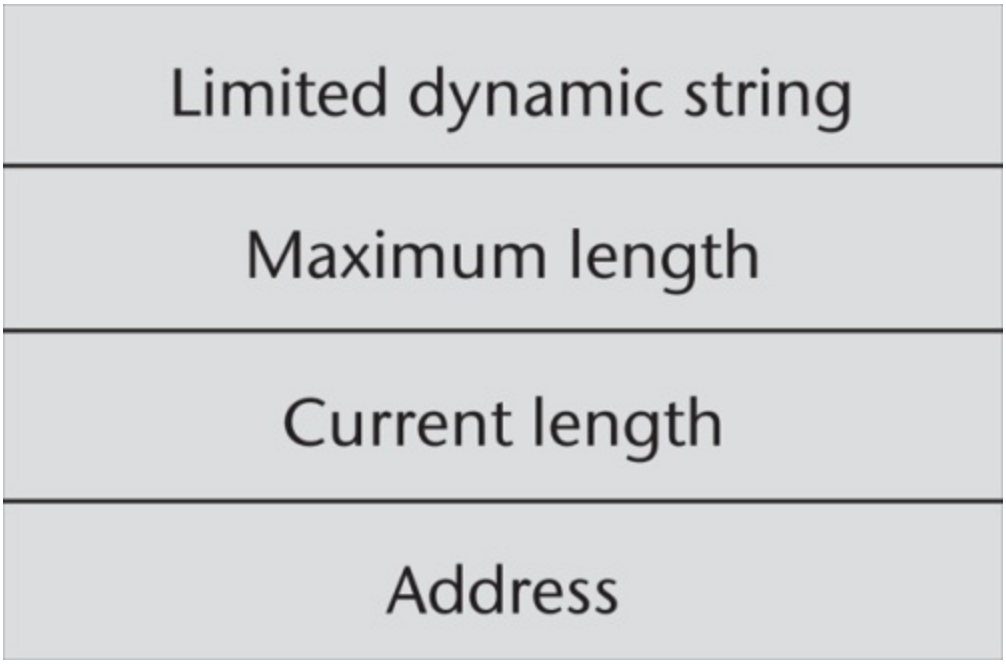

Figure 6.3 Run-time descriptor

for limited dynamic strings

The limited dynamic strings of C and C++ do not require run-time descriptors, because the end of a string is marked with the null character. They do not need the maximum length, because index values in array references are not range checked in these languages.

Static length and limited dynamic length strings require no special dynamic storage allocation. In the case of limited dynamic length strings, sufficient storage for the maximum length is allocated when the string variable is bound to storage, so only a single allocation process is involved.

Dynamic length strings require more complex storage management. The length of a string, and therefore the storage to which it is bound, must grow and shrink dynamically.

There are three approaches to supporting the dynamic allocation and deallocation that is required for dynamic length strings. First, strings can be stored in a linked list, so that when a string grows, the newly required cells can come from anywhere in the heap. The drawbacks to this method are the extra storage occupied by the links in the list representation and the necessary complexity of string operations.

The second approach is to store strings as arrays of pointers to individual characters allocated in the heap. This method still uses extra memory, but string processing can be faster than with the linked-list approach.

The third alternative is to store complete strings in adjacent storage cells. The problem with this method arises when a string grows: How can storage that is adjacent to the existing cells continue to be allocated for the string variable? Frequently, such storage is not available. Instead, a new area of memory is found that can store the complete new string, and the old part is moved to this area. Then, the memory cells used for the old string are deallocated. This latter approach is the one typically used. The general problem of managing allocation and deallocation of variable-size segments is discussed in Section 6.11.7.3.

Although the linked-list method requires more storage, the associated allocation and deallocation processes are simple. However, some string operations are slowed by the required pointer chasing. On the other hand, using adjacent memory for complete strings results in faster string operations and requires significantly less storage, but the allocation and deallocation processes are slower.

6.4 Enumeration Types

An **enumeration type** is one in which all of the possible values, which are named constants, are provided, or enumerated, in the definition. Enumeration types provide a way of defining and grouping collections of named constants, which are called **enumeration constants**. The definition of a typical enumeration type is shown in the following C# example:

```
enum  days {Mon, Tue, Wed, Thu, Fri, Sat, Sun};
```

The enumeration constants are typically implicitly assigned the integer values, 0, 1, . . . but can be explicitly assigned any integer literal in the type's definition.

6.4.1 Design Issues

The design issues for enumeration types are as follows:

- Is an enumeration constant allowed to appear in more than one type definition, and if so, how is the type of an occurrence of that constant in the program checked?
- Are enumeration values coerced to integer?
- Are any other types coerced to an enumeration type?

All of these design issues are related to type checking. If an enumeration variable is coerced to a numeric type, then there is little control over its range of legal operations or its range of values. If an `int` type value is coerced to an enumeration type, then an enumeration type variable could be assigned any integer value, whether it represented an enumeration constant or not.

6.4.2 Designs

In languages that do not have enumeration types, programmers usually simulate them with integer values. For example, suppose we needed to represent colors in a C program and C did not have an enumeration type. We might use 0 to represent blue, 1 to represent red, and so forth. These values could be defined as follows:

```
int    red = 0, blue = 1;
```

Now, in the program, we could use `red` and `blue` as if they were of a color type. The problem with this approach is that because we have not defined a type for our colors, there is no type checking when they are used. For example, it would be legal to add the two together, although that would rarely be an intended operation. They could also be combined with any other numeric type operand using any arithmetic operator, which would also rarely be useful. Furthermore, because they are just variables, they could be assigned any integer value, thereby destroying the relationship with the colors. This latter problem could be prevented by making them named constants.

C and Pascal were the first widely used languages to include an enumeration data type. C++ includes C's enumeration types. In C++, we could have the following:

```
enum  colors {red, blue, green, yellow, black};
colors myColor = blue, yourColor = red;
```

The `colors` type uses the default internal values for the enumeration constants, 0, 1, . . . , although the constants could have been specifically assigned any integer literal (or any constant-valued expression) by the programmer. The enumeration values are coerced to **`int`** when they are put in integer context. This allows their use in any numeric expression. For example, if the current value of `myColor` is `blue`, then the expression

```
myColor++
```

would assign the integer code for `green` to `myColor`.

C++ also allows enumeration constants to be assigned to variables of any numeric type, though that would likely be an error. However, no other type

value is coerced to an enumeration type in C++. For example,

```
myColor = 4;
```

is illegal in C++. This assignment would be legal if the right side had been cast to `colors` type. This prevents some potential errors.

C++ enumeration constants can appear in only one enumeration type in the same referencing environment.

In 2004, an enumeration type was added to Java in Java 5.0. All enumeration types in Java are implicitly subclasses of the predefined class `Enum`. Because enumeration types are classes, they can have instance data fields, constructors, and methods. Syntactically, Java enumeration type definitions appear like those of C++, except that they can include fields, constructors, and methods. The possible values of an enumeration are the only possible instances of the class. All enumeration types inherit `toString`, as well as a few other methods. An array of the instances of an enumeration type can be fetched with the static method `values`. The internal numeric value of an enumeration variable can be fetched with the `ordinal` method. No expression of any other type can be assigned to an enumeration variable. Also, an enumeration variable is never coerced to any other type.

C# enumeration types are like those of C++, except that they are never coerced to integer. So, operations on enumeration types are restricted to those that make sense. Also, the range of values is restricted to that of the particular enumeration type.

In ML, enumeration types are defined as new types with **`datatype`** declarations. For example, we could have the following:

```
datatype weekdays = Monday | Tuesday | Wednesday |
Thursday | Friday
```

The type of the elements of `weekdays` is integer.

F# has enumeration types that are similar to those of ML, except the reserved word **`type`** is used instead of **`datatype`** and the first value is preceded by an OR operator (`|`).

Swift has an enumeration type in which the enumeration values are names, which represent themselves, rather than having internal integer values. An enumeration type is defined in a structure that is similar to a switch structure, as in:

```
enum fruit {
  case orange
  case apple
  case banana
}
```

Dot notation is used to reference enumeration values, so in our example, the value of `apple` is referenced as `fruit.apple`.

Interestingly, none of the relatively recent scripting languages include enumeration types. These include Perl, JavaScript, PHP, Python, and Ruby. Even Java was a decade old before enumeration types were added.

6.4.3 Evaluation

Enumeration types can provide advantages in both readability and reliability. Readability is enhanced very directly: Named values are easily recognized, whereas coded values are not.

In the area of reliability, the enumeration types of C#, F#, Java 5.0, and Swift provide two advantages: (1) No arithmetic operations are legal on enumeration types; this prevents adding days of the week, for example, and (2) second, no enumeration variable can be assigned a value outside its defined range.4 If the `colors` enumeration type has 10 enumeration constants and uses `0..9` as its internal values, no number greater than `9` can be assigned to a `colors` type variable.

4. In C# and F#, an integer value can be cast to an enumeration type and assigned to the name of an enumeration variable. Such values must be tested with `Enum.IsDefined` method before assigning them to the name of an enumeration variable.

Because C treats enumeration variables like integer variables, it does not

provide either of these two advantages.

C++ is a little better. Numeric values can be assigned to enumeration type variables only if they are cast to the type of the assigned variable. Numeric values assigned to enumeration type variables are checked to determine whether they are in the range of the internal values of the enumeration type. Unfortunately, if the user uses a wide range of explicitly assigned values, this checking is not effective. For example,

```
enum  colors {red = 1, blue = 1000, green = 100000}
```

In this example, a value assigned to a variable of `colors` type will only be checked to determine whether it is in the range of `1..100000`.

6.5 Array Types

An **array** is a homogeneous aggregate of data elements in which an individual element is identified by its position in the aggregate, relative to the first element. The individual data elements of an array are of the same type. References to individual array elements are specified using subscript expressions. If any of the subscript expressions in a reference include variables, then the reference will require an additional run-time calculation to determine the address of the memory location being referenced.

In many languages, such as C, C++, Java, and C#, all of the elements of an array are required to be of the same type. In these languages, pointers and references are restricted to point to or reference a single type. So the objects or data values being pointed to or referenced are also of a single type. In some other languages, such as JavaScript, Python, and Ruby, variables are typeless references to objects or data values. In these cases, arrays still consist of elements of a single type, but the elements can reference objects or data values of different types. Such arrays are still homogeneous, because the array elements are of the same type. In Swift, arrays can be typed, that is, they will contain values only of a single type, or untyped, which means they can contain values of any type.

C# and Java 5.0 provide generic arrays, that is, arrays whose elements are references to objects, through their class libraries. These are discussed in Section 6.5.3.

6.5.1 Design Issues

The primary design issues specific to arrays are the following:

- What types are legal for subscripts?
- Are subscripting expressions in element references range checked?

- When are subscript ranges bound?
- When does array allocation take place?
- Are ragged or rectangular multidimensioned arrays allowed, or both?
- Can arrays be initialized when they have their storage allocated?
- What kinds of slices are allowed, if any?

In the following sections, examples of the design choices made for the arrays of the most common programming languages are discussed.

6.5.2 Arrays and Indices

Specific elements of an array are referenced by means of a two-level syntactic mechanism, where the first part is the aggregate name, and the second part is a possibly dynamic selector consisting of one or more items known as **subscripts** or **indices**. If all of the subscripts in a reference are constants, the selector is static; otherwise, it is dynamic. The selection operation can be thought of as a mapping from the array name and the set of subscript values to an element in the aggregate. Indeed, arrays are sometimes called **finite mappings**. Symbolically, this mapping can be shown as

history note

The designers of pre-90 Fortrans and PL/I chose parentheses for array subscripts because no other suitable characters were available at the time. Card punches did not include bracket characters.

array_name(subscript_value_list) → element

The syntax of array references is fairly universal: The array name is followed by the list of subscripts, which is surrounded by either parentheses or brackets. In some languages that provide multidimensioned arrays as arrays

of arrays, each subscript appears in its own brackets. A problem with using parentheses to enclose subscript expressions is that they often are also used to enclose the parameters in subprogram calls; this use makes references to arrays appear exactly like those calls. For example, consider the following Ada assignment statement:

```
Sum := Sum + B(I);
```

Because parentheses are used for both subprogram parameters and array subscripts in Ada, both program readers and compilers are forced to use other information to determine whether `B(I)` in this assignment is a function call or a reference to an array element. This results in reduced readability.

history note

Fortran I limited the number of array subscripts to three, because at the time of the design, execution efficiency was a primary concern. Fortran I designers had developed a very fast method for accessing the elements of arrays of up to three dimensions, using the three index registers of the IBM 704. Fortran IV was first implemented on an IBM 7094, which had seven index registers. This allowed Fortran IV's designers to allow arrays with up to seven subscripts. Most other contemporary languages enforce no such limits.

The designers of Ada specifically chose parentheses to enclose subscripts so there would be uniformity between array references and function calls in expressions, in spite of potential readability problems. They made this choice in part because both array element references and function calls are mappings. Array element references map the subscripts to a particular element of the array. Function calls map the actual parameters to the function definition and, eventually, a functional value.

Most languages other than Fortran and Ada use brackets to delimit their array indices.

Two distinct types are involved in an array type: the element type and the type of the subscripts. The type of the subscripts is often integer.

Early programming languages did not specify that subscript ranges must be implicitly checked. Range errors in subscripts are common in programs, so requiring range checking is an important factor in the reliability of languages. Many contemporary languages also do not specify range checking of subscripts, but Java, ML, and C# do.

Subscripting in Perl is a bit unusual in that although the names of all arrays begin with at signs (@), because array elements are always scalars and the names of scalars always begin with dollar signs ($), references to array elements use dollar signs rather than at signs in their names. For example, for the array `@list`, the second element is referenced with `$list`[1].

One can reference an array element in Perl with a negative subscript, in which case the subscript value is an offset from the end of the array. For example, if the array `@list` has five elements with the subscripts 0..4, `$list` [−2] references the element with the subscript 3. A reference to a nonexistent element in Perl yields **`undef`**, but no error is reported.

6.5.3 Subscript Bindings and Array Categories

The binding of the subscript type to an array variable is usually static, but the subscript value ranges are sometimes dynamically bound.

In some languages, the lower bound of the subscript range is implicit. For example, in the C-based languages, the lower bound of all subscript ranges is fixed at `0`. In some other languages, the lower bounds of the subscript ranges must be specified by the programmer.

There are four categories of arrays, based on the binding to subscript ranges, the binding to storage, and from where the storage is allocated. The category names indicate the design choices of these three. In the first three of these categories, once the subscript ranges are bound and the storage is allocated, they remain fixed for the lifetime of the variable. Of course, when the subscript ranges are fixed, the array cannot change size.

A **static array** is one in which the subscript ranges are statically bound and storage allocation is static (done before run time). The advantage of static arrays is efficiency: No dynamic allocation or deallocation is required. The disadvantage is that the storage for the array is fixed for the entire execution time of the program.

A **fixed stack-dynamic array** is one in which the subscript ranges are statically bound, but the allocation is done at declaration elaboration time during execution. The advantage of fixed stack-dynamic arrays over static arrays is space efficiency. A large array in one subprogram can use the same space as a large array in a different subprogram, as long as both subprograms are not active at the same time. The same is true if the two arrays are in different blocks that are not active at the same time. The disadvantage is the required allocation and deallocation time.

A **fixed heap-dynamic array** is similar to a fixed stack-dynamic array, in that the subscript ranges and the storage binding are both fixed after storage is allocated. The differences are that both the subscript ranges and storage bindings are done when the user program requests them during execution, and the storage is allocated from the heap, rather than the stack. The advantage of fixed heap-dynamic arrays is flexibility—the array's size always fits the problem. The disadvantage is allocation time from the heap, which is longer than allocation time from the stack.

A **heap-dynamic array** is one in which the binding of subscript ranges and storage allocation is dynamic and can change any number of times during the array's lifetime. The advantage of heap-dynamic arrays over the others is flexibility: Arrays can grow and shrink during program execution as the need for space changes. The disadvantage is that allocation and deallocation take longer and may happen many times during execution of the program. Examples of the four categories are given in the following paragraphs.

Arrays declared in C and C++ functions that include the **`static`** modifier are static.

Arrays that are declared in C and C++ functions without the **`static`** specifier are examples of fixed stack-dynamic arrays.

C and C++ also provide fixed heap-dynamic arrays. The standard C library functions `malloc` and `free`, which are general heap allocation and deallocation operations, respectively, can be used for C arrays. C++ uses the operators **`new`** and **`delete`** to manage heap storage. An array is treated as a pointer to a collection of storage cells, where the pointer can be indexed, as discussed in Section 6.11.5.

In Java, all non-generic arrays are fixed heap-dynamic. Once created, these arrays keep the same subscript ranges and storage. C# also provides fixed heap-dynamic arrays.

Objects of the C# `List` class are generic heap-dynamic arrays. These array objects are created without any elements, as in

```
List<String> stringList =  new  List<String>();
```

Elements are added to this object with the `Add` method, as in

```
stringList.Add("Michael");
```

Access to elements of these arrays is through subscripting.

Java includes a generic class similar to C#'s `List`, named `ArrayList`. It is different from C#'s `List` in that subscripting is not supported—`get` and `set` methods must be used to access the elements.

A Perl array can be made to grow by using the `push` (puts one or more new elements on the end of the array) and `unshift` (puts one or more new elements on the beginning of the array), or by assigning a value to the array specifying a subscript beyond the highest current subscript of the array. An array can be made to shrink to no elements by assigning it the empty list, `()`. The length of an array is defined to be the largest subscript plus one.

Like Perl, JavaScript allows arrays to grow with the `push` and `unshift` methods and shrink by setting them to the empty list. However, negative subscripts are not supported.

JavaScript arrays can be sparse, meaning the subscript values need not be contiguous. For example, suppose we have an array named list that has 10

elements with the subscripts 0..9.[5] Consider the following assignment statement:

5. The subscript range could just as easily have been 1000 .. 1009.

```
list[50] = 42;
```

Now, `list` has 11 elements and length 51. The elements with subscripts `11..49` are not defined and therefore do not require storage. A reference to a nonexistent element in a JavaScript array yields **`undefined`**.

Arrays in Python and Ruby can be made to grow only through methods to add elements or catenate other arrays. Ruby and Perl support negative subscripts, but Python does not. In Python an element or slice of an array can be deleted. A reference to a nonexistent element in Python results in a run-time error, whereas a similar reference in Ruby yields **`nil`** and no error is reported.

Swift dynamic arrays are objects that use integer subscripts, beginning at zero, and include several useful methods. The `append` method adds an element to the end of an array. The `insert` method inserts a new element at any position in the array, but results in an error if the insertion is at a subscript beyond the current length of the array. Elements can be removed from an array with the `removeAtIndex` method. There are also `reverse` and `count` methods.

Although the ML definition does not include arrays, its widely used implementation, SML/NJ, does.

The only predefined collection type that is part of F# is the array (other collection types are provided through the .NET Framework Library). These arrays are like those of C#. A **`foreach`** statement is included in the language for array processing.

6.5.4 Array Initialization

Some languages provide the means to initialize arrays at the time their

storage is allocated. C, C++, Java, Swift, and C# allow initialization of their arrays. Consider the following C declaration:

```
int  list [] = {4, 5, 7, 83};
```

The array `list` is created and initialized with the values `4`, `5`, `7`, and `83`. The compiler also sets the length of the array. This is meant to be a convenience but is not without cost. It effectively removes the possibility that the system could detect some kinds of programmer errors, such as mistakenly leaving a value out of the list.

As discussed in Section 6.3.2, character strings in C and C++ are implemented as arrays of **`char`**. These arrays can be initialized to string constants, as in

```
char  name [] = "freddie";
```

The array `name` will have eight elements, because all strings are terminated with a null character (zero), which is implicitly supplied by the system for string constants.

Arrays of strings in C and C++ can also be initialized with string literals. For example,

```
char  *names [] = {"Bob", "Jake", "Darcie"};
```

This example illustrates the nature of character literals in C and C++. In the previous example of a string literal being used to initialize the **`char`** array `name`, the literal is taken to be a **`char`** array. But in the latter example (`names`), the literals are taken to be pointers to characters, so the array is an array of pointers to characters. For example, `names[0]` is a pointer to the letter `'B'` in the literal character array that contains the characters `'B'`, `'o'`, `'b'`, and the null character.

In Java, similar syntax is used to define and initialize an array of references to `String` objects. For example,

```
String[] names = ["Bob", "Jake", "Darcie"];
```

6.5.5 Array Operations

An array operation is one that operates on an array as a unit. The most common array operations are assignment, catenation, comparison for equality and inequality, and slices, which are discussed separately in Section 6.5.5.

The C-based languages do not provide any array operations, except through the methods of Java, C++, and C#. Perl supports array assignments but does not support comparisons.

Python's arrays are called lists, although they have all the characteristics of dynamic arrays. Because the objects can be of any types, these arrays are heterogeneous. Python provides array assignment, although it is only a reference change. Python also has operations for array catenation (+) and element membership (**`in`**). It includes two different comparison operators: one that determines whether the two variables reference the same object (**`is`**) and one that compares all corresponding objects in the referenced objects, regardless of how deeply they are nested, for equality (==).

Like Python, the elements of Ruby's arrays are references to objects. And like Python, when a == operator is used between two arrays, the result is true only if the two arrays have the same length and the corresponding elements are equal. Ruby's arrays can be catenated with an `Array` method.

F# includes many array operators in its `Array` module. Among these are `Array.append`, `Array.copy`, and `Array.length`.

Arrays and their operations are the heart of APL; it is the most powerful array-processing language ever devised. Because of its relative obscurity and its lack of effect on subsequent languages, however, we present here only a glimpse into its array operations.

In APL, the four basic arithmetic operations are defined for vectors (single-dimensioned arrays) and matrices, as well as scalar operands. For example,

```
A + B
```

is a valid expression, whether A and B are scalar variables, vectors, or matrices.

APL includes a collection of unary operators for vectors and matrices, some of which are as follows (where V is a vector and M is a matrix):

⌽V	reverses the elements of V
⌽M	reverses the columns of M
⊖M	reverses the rows of M
⍉M	transposes M (its rows become its columns and vice versa)
⌹M	inverts M

APL also includes several special operators that take other operators as operands. One of these is the inner product operator, which is specified with a period (.). It takes two operands, which are binary operators. For example,

```
+.×
```

is a new operator that takes two arguments, either vectors or matrices. It first multiplies the corresponding elements of two arguments, and then it sums the results. For example, if A and B are vectors,

```
A × B
```

is the mathematical inner product of A and B (a vector of the products of the corresponding elements of A and B). The statement

```
A +.× B
```

is the sum of the inner product of A and B. If A and B are matrices, this expression specifies the matrix multiplication of A and B.

The special operators of APL are actually functional forms, which are described in Chapter 15.

6.5.6 Rectangular and Jagged

Arrays

A **rectangular array** is a multidimensioned array in which all of the rows have the same number of elements and all of the columns have the same number of elements. Rectangular arrays model rectangular tables exactly.

A **jagged array** is one in which the lengths of the rows need not be the same. For example, a jagged matrix may consist of three rows, one with 5 elements, one with 7 elements, and one with 12 elements. This also applies to the columns and higher dimensions. So, if there is a third dimension (layers), each layer can have a different number of elements. Jagged arrays are made possible when multidimensioned arrays are actually arrays of arrays. For example, a matrix would appear as an array of single-dimensioned arrays.

C, C++, and Java support jagged arrays but not rectangular arrays. In those languages, a reference to an element of a multidimensioned array uses a separate pair of brackets for each dimension. For example,

```
myArray[3][7]
```

C# and F# support both rectangular and jagged arrays. For rectangular arrays, all subscript expressions in references to elements are placed in a single pair of brackets. For example,

```
myArray[3, 7]
```

6.5.7 Slices

A **slice** of an array is some substructure of that array. For example, if `A` is a matrix, then the first row of `A` is one possible slice, as are the last row and the first column. It is important to realize that a slice is not a new data type. Rather, it is a mechanism for referencing part of an array as a unit. If arrays cannot be manipulated as units in a language, that language has no use for slices.

Consider the following Python declarations:

```
vector = [2, 4, 6, 8, 10, 12, 14, 16]
mat = [[1, 2, 3],[4, 5, 6],[7, 8, 9]]
```

Recall that the default lower bound for Python arrays is 0. The syntax of a Python slice reference is a pair of numeric expressions separated by a colon. The first is the first subscript of the slice; the second is the first subscript after the last subscript in the slice. Therefore, `vector[3:6]` is a three-element array with the fourth through sixth elements of `vector` (those elements with the subscripts `3`, `4`, and `5`). A row of a matrix is specified by giving just one subscript. For example, `mat[1]` refers to the second row of `mat`; a part of a row can be specified with the same syntax as a part of a single-dimensioned array. For example, `mat[0][0:2]` refers to the first and second element of the first row of mat, which is `[1, 2]`.

Python also supports more complex slices of arrays. For example, `vector[0:7:2]` references every other element of `vector`, up to but not including the element with the subscript 7, starting with the subscript `0`, which is `[2, 6, 10, 14]`.

Perl supports slices of two forms, a list of specific subscripts or a range of subscripts. For example,

```
@list[1..5] = @list2[3, 5, 7, 9, 13];
```

Notice that slice references use array names, not scalar names, because slices are arrays (not scalars).

Ruby supports slices with the `slice` method of its `Array` object, which can take three forms of parameters. A single integer expression parameter is interpreted as a subscript, in which case `slice` returns the element with the given subscript. If `slice` is given two integer expression parameters, the first is interpreted as a beginning subscript and the second is interpreted as the number of elements in the slice. For example, suppose `list` is defined as follows:

```
list = [2, 4, 6, 8, 10]
```

`list.slice(2, 2)` returns `[6, 8]`. The third parameter form for `slice` is a range, which has the form of an integer expression, two periods, and a second

integer expression. With a range parameter, `slice` returns an array of the element with the given range of subscripts. For example, `list.slice (1..3)` returns `[4, 6, 8]`.

6.5.8 Evaluation

Arrays have been included in virtually all programming languages. The primary advances since their introduction in Fortran I have been slices and dynamic arrays. As discussed in Section 6.6, the latest advances in arrays have been in associative arrays.

6.5.9 Implementation of Array Types

Implementing arrays requires considerably more compile-time effort than does implementing primitive types. The code to allow accessing of array elements must be generated at compile time. At run time, this code must be executed to produce element addresses. There is no way to precompute the address to be accessed by a reference such as

```
list[k]
```

A single-dimensioned array is implemented as a list of adjacent memory cells. Suppose the array `list` is defined to have a subscript range lower bound of `0`. The access function for `list` is often of the form

- address (`list[k]`) = address (`list[0]`) + `k` * element_size

where the first operand of the addition is the constant part of the access function, and the second is the variable part.

If the element type is statically bound and the array is statically bound to storage, then the value of the constant part can be computed before run time. However, the addition and multiplication operations must be done at run

time.

The generalization of this access function for an arbitrary lower bound is

- address (`list[k]`) = address (`list`[lower_bound]) +
- ((`k` −lower_bound) * element_size)

The compile-time descriptor for single-dimensioned arrays can have the form shown in Figure 6.4. The descriptor includes information required to construct the access function. If run-time checking of index ranges is not done and the attributes are all static, then only the access function is required during execution; no descriptor is needed. If run-time checking of index ranges is done, then those index ranges may need to be stored in a run-time descriptor. If the subscript ranges of a particular array type are static, then the ranges may be incorporated into the code that does the checking, thus eliminating the need for the run-time descriptor. If any of the descriptor entries are dynamically bound, then those parts of the descriptor must be maintained at run time.

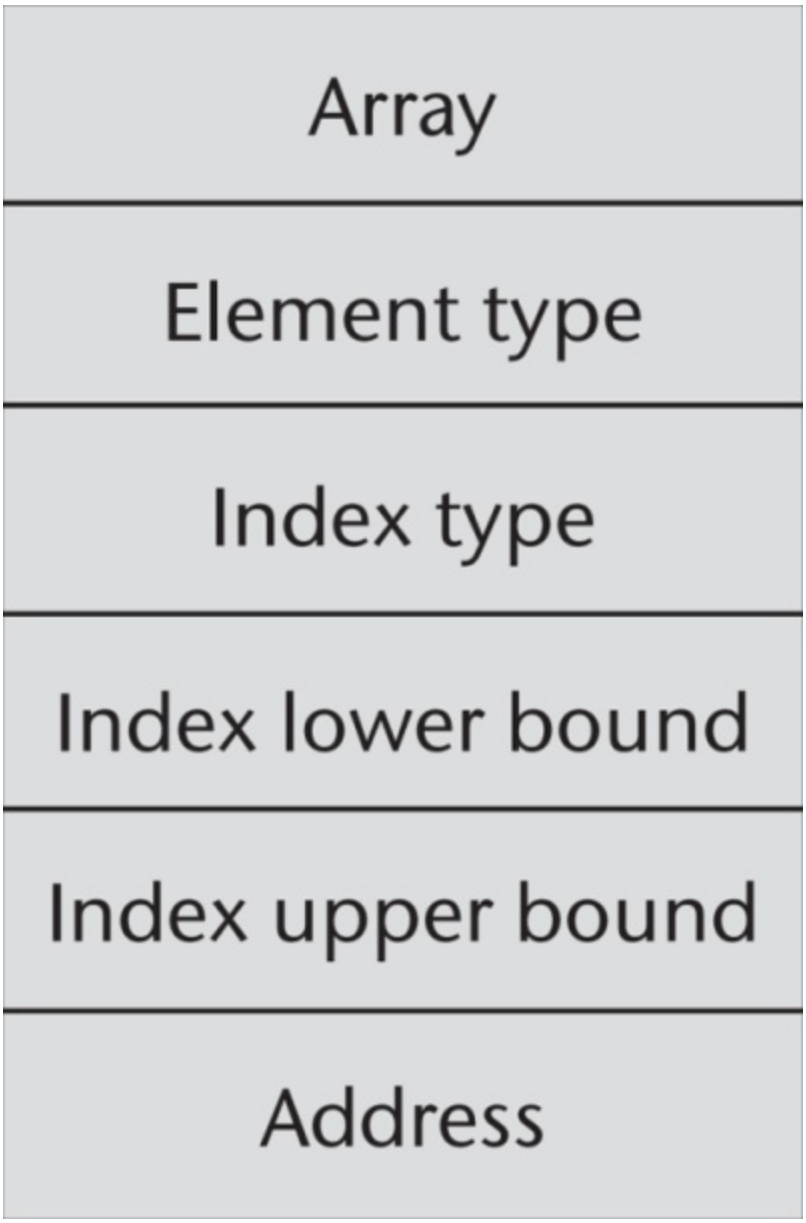

Figure 6.4 Compile-time descriptor for single-dimensioned arrays

True multidimensional arrays, that is, those that are not arrays of arrays, are more complex to implement than single-dimensioned arrays, although the

extension to more dimensions is straightforward. Hardware memory is linear—just a simple sequence of bytes. So values of data types that have two or more dimensions must be mapped onto the single-dimensioned memory. There are two ways in which multidimensional arrays can be mapped to one dimension: row major order and column major order (not used in any widely used language). In **row major order**, the elements of the array that have as their first subscript the lower bound value of that subscript are stored first, followed by the elements of the second value of the first subscript, and so forth. If the array is a matrix, it is stored by rows. For example, if the matrix had the values

3 4 7

6 2 5

1 3 8

it would be stored in row major order as

3, 4, 7, 6, 2, 5, 1, 3, 8

The access function for a multidimensional array is the mapping of its base address and a set of index values to the address in memory of the element specified by the index values. The access function for two-dimensional arrays stored in row major order can be developed as follows. In general, the address of an element is the base address of the structure plus the element size times the number of elements that precede it in the structure. For a matrix in row major order, the number of elements that precede an element is the number of rows above the element times the size of a row, plus the number of elements to the left of the element in its row. This is illustrated in Figure 6.5, in which we assume that subscript lower bounds are all zero.

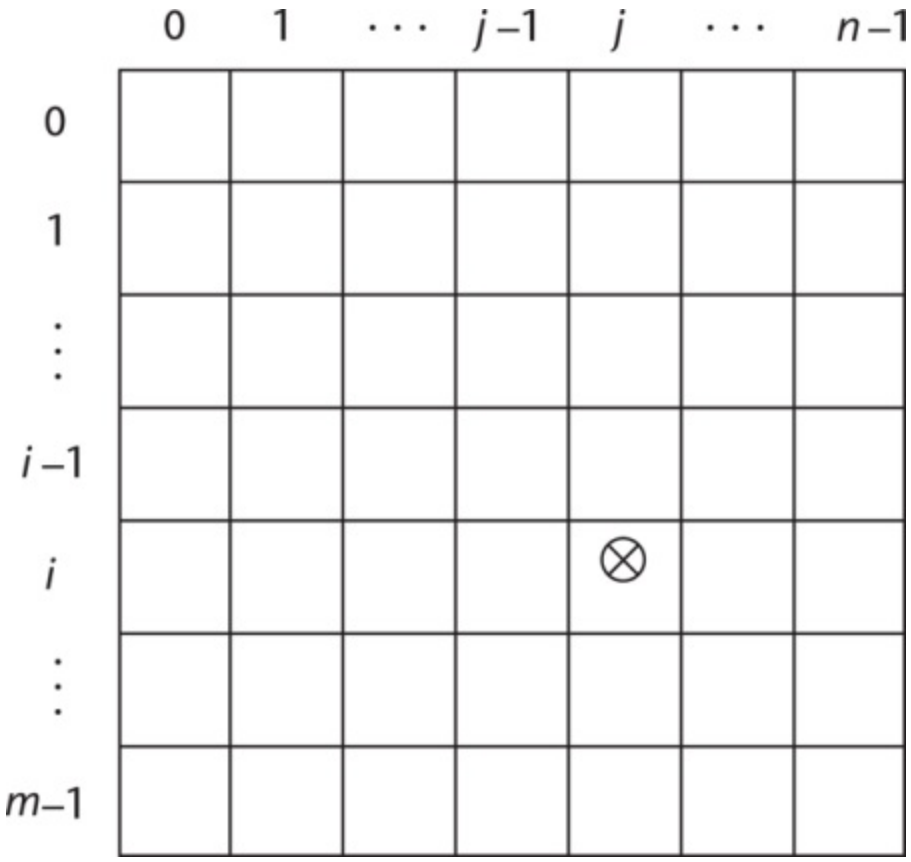

Figure 6.5 The location of the `[i,j]` element in a matrix

Figure 6.5 Full Alternative Text

To get an actual address value, the number of elements that precede the desired element must be multiplied by the element size. Now, the access function can be written as

- location(`a[i,j]`) = address of `a[0, 0]`
- + ((((number of rows above the `i`*th* row) * (size of a row))
- + (number of elements left of the `j`*th* column)) *

- element size)

Because the number of rows above the `i`*th* row is `i` and the number of elements to the left of the `j`*th* column is `j`, we have

- location(`a[i, j]`) = address of `a[0, 0]` + (((`i` * `n`) + `j`) *
- element_size)

where `n` is the number of elements per row. The first term is the constant part and the last is the variable part.

The generalization to arbitrary lower bounds results in the following access function:

- location(`a[i, j]`) = address of a[row_lb, col_lb]
- = (((`i` − row_lb) * n) + (`j` − col_lb)) * element_size

where row_lb is the lower bound of the rows and col_lb is the lower bound of the columns. This can be rearranged to the form

- location(`a[i, j]`) = address of a[row_lb, col_lb]
- − (((row_lb * n) + col_lb) * element_size)
- + (((`i` * `n`) + `j`) * element_size)

where the first two terms are the constant part and the last is the variable part. This can be generalized rather easily to an arbitrary number of dimensions.

For each dimension of an array, one add and one multiply instruction are required for the access function. Therefore, accesses to elements of arrays with several subscripts are costly. The compile-time descriptor for a multidimensional array is shown in Figure 6.6.

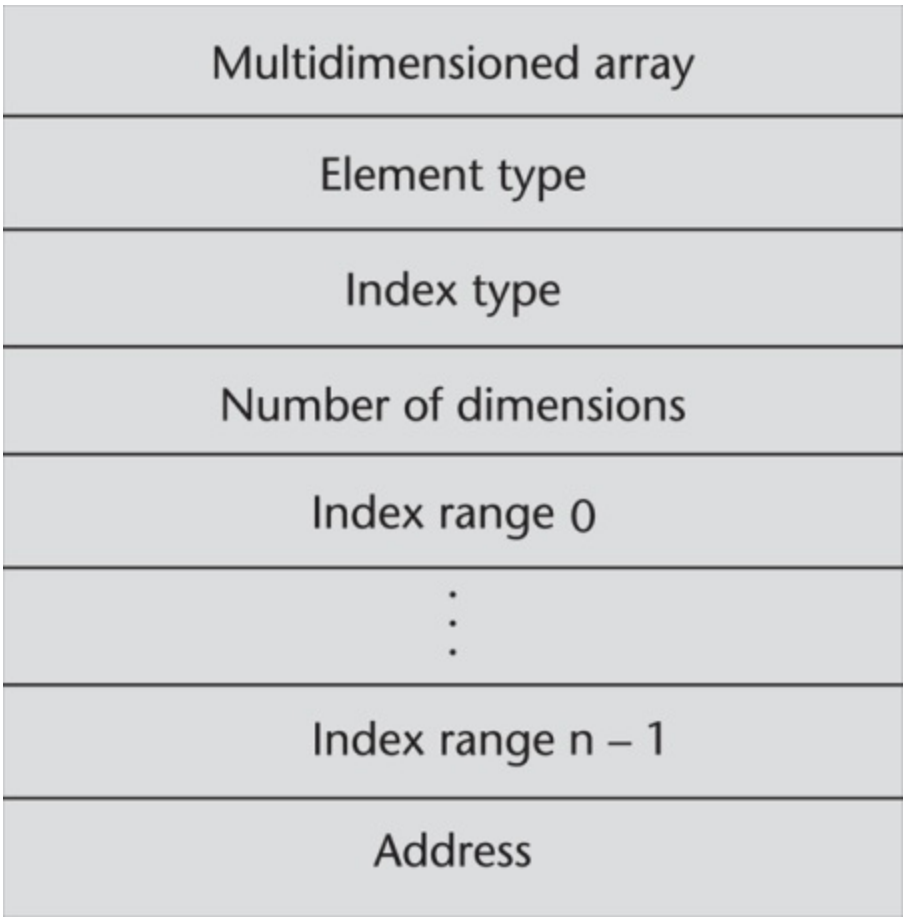

Figure 6.6 A compile-time - descriptor for a - multidimensional array

6.6 Associative Arrays

An **associative array** is an unordered collection of data elements that are indexed by an equal number of values called **keys**. In the case of non--associative arrays, the indices never need to be stored (because of their regularity). In an associative array, however, the user-defined keys must be stored in the structure. So each element of an associative array is in fact a pair of entities, a key and a value. We use Perl's design of associative arrays to illustrate this data structure. Associative arrays are also supported directly by Python, Ruby, and Swift and by the standard class libraries of Java, C++, C#, and F#.

The only design issue that is specific for associative arrays is the form of references to their elements.

6.6.1 Structure and Operations

In Perl, associative arrays are called **hashes**, because in the implementation their elements are stored and retrieved with hash functions. The namespace for Perl hashes is distinct: Every hash variable name must begin with a percent sign (`%`). Each hash element consists of two parts: a key, which is a string, and a value, which is a scalar (number, string, or reference). Hashes can be set to literal values with the assignment statement, as in

```
%salaries = ("Gary" => 75000, "Perry" => 57000,
             "Mary" => 55750, "Cedric" => 47850);
```

Individual element values are referenced using notation that is similar to that used for Perl arrays. The key value is placed in braces and the hash name is replaced by a scalar variable name that is the same except for the first character. Although hashes are not scalars, the value parts of hash elements are scalars, so references to hash element values use scalar names. Recall that scalar variable names begin with dollar signs (`$`). So, an assignment of `58850` to the element of `%salaries` with the key `"Perry"` would appear as follows:

```
$salaries{"Perry"} = 58850;
```

A new element is added using the same assignment statement form. An element can be removed from the hash with the **`delete`** operator, as in the following:

```
delete $salaries{"Gary"};
```

The entire hash can be emptied by assigning the empty literal to it, as in the following:

```
@salaries = ();
```

The size of a Perl hash is dynamic: It grows when an element is added and shrinks when an element is deleted, and also when it is emptied by assignment of the empty literal. The `exists` operator returns true or false, depending on whether its operand key is an element in the hash. For example,

```
if (exists $salaries{"Shelly"}) . . .
```

The `keys` operator, when applied to a hash, returns an array of the keys of the hash. The `values` operator does the same for the values of the hash. The `each` operator iterates over the element pairs of a hash.

Python's associative arrays, which are called **dictionaries**, are similar to those of Perl, except the values are all references to objects. The associative arrays supported by Ruby are similar to those of Python, except that the keys can be any object,[6] rather than just strings. There is a progression from Perl's hashes, in which the keys must be strings, to PHP's arrays, in which the keys can be integers or strings, to Ruby's hashes, in which any type object can be a key.

6. Objects that change do not make good keys, because the changes could change the hash function value. Therefore, arrays and hashes are never used as keys.

PHP's arrays are both normal arrays and associative arrays. They can be treated as either. The language provides functions that allow both indexed and hashed access to elements. An array can have elements that are created

with simple numeric indices and elements that are created with string hash keys.

Swift’s associative arrays are called dictionaries. The keys can be of one specific type, but the values can be of mixed types, in which case they are objects.

An associative array is much better than an array if searches of the elements are required, because the implicit hashing operation used to access elements is very efficient. Furthermore, associative arrays are ideal when the data to be stored is paired, as with employee names and their salaries. On the other hand, if every element of a list must be processed, it is more efficient to use an array.

6.6.2 Implementing Associative Arrays

The implementation of Perl’s associative arrays is optimized for fast lookups, but it also provides relatively fast reorganization when array growth requires it. A 32-bit hash value is computed for each entry and is stored with the entry, although an associative array initially uses only a small part of the hash value. When an associative array must be expanded beyond its initial size, the hash function need not be changed; rather, more bits of the hash value are used. Only half of the entries must be moved when this happens. So, although expansion of an associative array is not free, it is not as costly as might be expected.

The elements in PHP’s arrays are placed in memory through a hash function. However, all elements are linked together in the order in which they were created. The links are used to support iterative access to elements through the `current` and `next` functions.

6.7 Record Types

A **record** is an aggregate of data elements in which the individual elements are identified by names and accessed through offsets from the beginning of the structure.

There is frequently a need in programs to model a collection of data in which the individual elements are not of the same type or size. For example, information about a college student might include name, student number, grade point average, and so forth. A data type for such a collection might use a character string for the name, an integer for the student number, a floating-point for the grade point average, and so forth. Records are designed for this kind of need.

It may appear that records and heterogeneous arrays are the same, but that is not the case. The elements of a heterogeneous array are all references to data objects that reside in scattered locations, often on the heap. The elements of a record are of potentially different sizes and reside in adjacent memory locations.

Records have been part of all of the most popular programming languages, except pre-90 versions of Fortran, since the early 1960s, when they were introduced by COBOL. In some languages that support object-oriented programming, data classes serve as records.

In C, C++, C#, and Swift, records are supported with the `struct` data type. In C++, structures are a minor variation on classes. In C#, structs also are related to classes, but are quite different from them. C# structs are stack--allocated value types, as opposed to class objects, which are heap-allocated reference types. Structs in C++ and C# are normally used as encapsulation structures, rather than data structures. They are further discussed in this capacity in Chapter 11. Structs are also included in ML and F#.

In Python and Ruby, records can be implemented as hashes, which themselves can be elements of arrays.

The following sections describe how records are declared or defined, how references to fields within records are made, and the common record operations.

The following design issues are specific to records:

- What is the syntactic form of references to fields?
- Are elliptical references allowed?

6.7.1 Definitions of Records

The fundamental difference between a record and an array is that record elements, or **fields**, are not referenced by indices. Instead, the fields are named with identifiers, and references to the fields are made using these identifiers. Another difference between arrays and records is that records in some languages are allowed to include unions, which are discussed in Section 6.10.

The COBOL form of a record declaration, which is part of the data division of a COBOL program, is illustrated in the following example:

```
01  EMPLOYEE-RECORD.
    02  EMPLOYEE-NAME.
        05  FIRST   PICTURE IS X(20).
        05  Middle  PICTURE IS X(10).
        05  LAST    PICTURE IS X(20).
    02  HOURLY-RATE PICTURE IS 99V99.
```

The `EMPLOYEE-RECORD` record consists of the `EMPLOYEE-NAME` record and the `HOURLY-RATE` field. The numerals `01`, `02`, and `05` that begin the lines of the record declaration are **level numbers**, which indicate by their relative values the hierarchical structure of the record. Any line that is followed by a line with a higher-level number is itself a record. The `PICTURE` clauses show the formats of the field storage locations, with `X(20)` specifying 20 alphanumeric characters and `99V99` specifying four decimal digits with the decimal point in the middle.

In Java, records can be defined as data classes, with nested records defined as nested classes. Data members of such classes serve as the record fields.

6.7.2 References to Record Fields

References to the individual fields of records are syntactically specified by several different methods, two of which name the desired field and its enclosing records. COBOL field references have the form

- field_name `OF` record_name_1 `OF . . . OF` record_name_n

where the first record named is the smallest or innermost record that contains the field. The next record name in the sequence is that of the record that contains the previous record, and so forth. For example, the `Middle` field in the COBOL record example above can be referenced with

```
Middle OF EMPLOYEE-NAME OF EMPLOYEE-RECORD
```

Most of the other languages use **dot notation** for field references, where the components of the reference are connected with periods. Names in dot notation have the opposite order of COBOL references: They use the name of the largest enclosing record first and the field name last. For example, if `Middle` is a field in the `Employee_Name` record which is embedded in the `Employee_Record` record, it would be referenced with the following:

```
Employee_Record.Employee_Name.Middle
```

A **fully qualified reference** to a record field is one in which all intermediate record names, from the largest enclosing record to the specific field, are named in the reference. In the COBOL example above the field reference is fully qualified. As an alternative to fully qualified references, COBOL allows **elliptical references** to record fields. In an elliptical reference, the field is named, but any or all of the enclosing record names can be omitted, as long as the resulting reference is unambiguous in the referencing environment. For example, `FIRST`, `FIRST OF EMPLOYEE-NAME`, and `FIRST OF EMPLOYEE-RECORD` are elliptical references to the employee's first name in the COBOL record declared above. Although elliptical references are a programmer

convenience, they require a compiler to have elaborate data structures and procedures in order to correctly identify the referenced field. They are also somewhat detrimental to readability.

6.7.3 Evaluation

Records are frequently valuable data types in programming languages. The design of record types is straightforward, and their use is safe.

Records and arrays are closely related structural forms, and therefore it is interesting to compare them. Arrays are used when all the data values have the same type and/or are processed in the same way. This processing is easily done when there is a systematic way of sequencing through the structure. Such processing is well supported by using dynamic subscripting as the addressing method.

Records are used when the collection of data values is heterogeneous and the different fields are not processed in the same way. Also, the fields of a record often need not be processed in a particular order. Field names are like literal, or constant, subscripts. Because they are static, they provide very efficient access to the fields. Dynamic subscripts could be used to access record fields, but it would disallow type checking and would also be slower.

Records and arrays represent thoughtful and efficient methods of fulfilling two separate but related applications of data structures.

6.7.4 Implementation of Record Types

The fields of records are stored in adjacent memory locations. But because the sizes of the fields are not necessarily the same, the access method used for arrays is not used for records. Instead, the offset address, relative to the beginning of the record, is associated with each field. Field accesses are all handled using these offsets. The compile-time descriptor for a record has the

general form shown in Figure 6.7. Run-time descriptors for records are unnecessary.

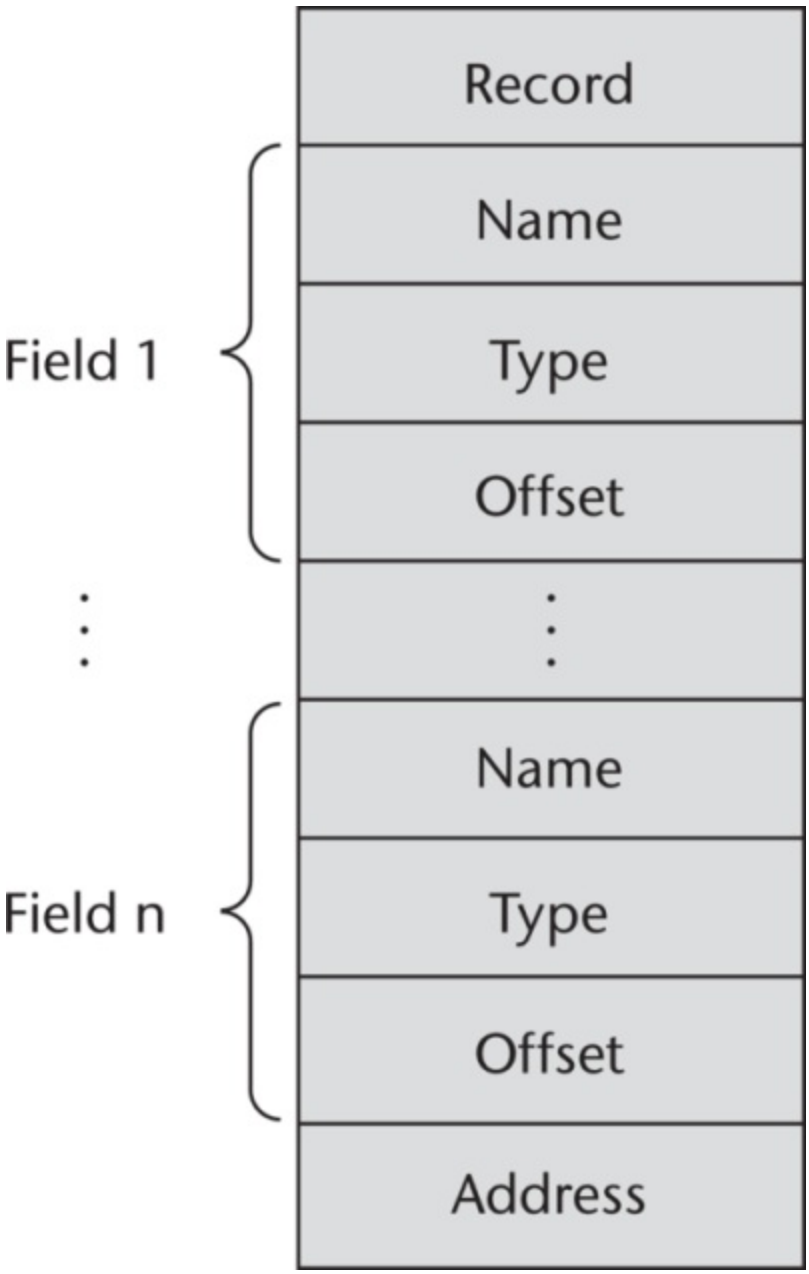

Figure 6.7 A compile-time - descriptor for a record

Figure 6.7 Full Alternative Text

6.8 Tuple Types

A tuple is a data type that is similar to a record, except that the elements are not named.

Python includes an immutable tuple type. If a tuple needs to be changed, it can be converted to an array with the `list` function. After the change, it can be converted back to a tuple with the `tuple` function. One use of tuples is when an array must be write protected, such as when it is sent as a parameter to an external function and the user does not want the function to be able to modify the parameter.

Python's tuples are closely related to its lists, except that tuples are immutable. A tuple is created by assigning a tuple literal, as in the following example:

```
myTuple = (3, 5.8, 'apple')
```

Notice that the elements of a tuple need not be of the same type.

The elements of a tuple can be referenced with indexing in brackets, as in the following:

```
myTuple[1]
```

This references the first element of the tuple, because tuple indexing begins at `1`.

Tuples can be catenated with the plus (+) operator. They can be deleted with the **`del`** statement. There are also other operators and functions that operate on tuples.

ML includes a tuple data type. An ML tuple must have at least two elements, whereas Python's tuples can be empty or contain one element. As in Python, an ML tuple can include elements of mixed types. The following statement creates a tuple:

```
val myTuple = (3, 5.8, 'apple');
```

The syntax of a tuple element access is as follows:

```
#1(myTuple);
```

This references the first element of the tuple.

A new tuple type can be defined in ML with a type declaration, such as the following:

```
type intReal = int * real;
```

Values of this type consist of an integer and a real. The asterisk can be misleading. It is used to separate the tuple components, indicating a type product, and has nothing to do with arithmetic.

F# also has tuples. A tuple is created by assigning a tuple value, which is a list of expressions separated by commas and delimited by parentheses, to a name in a **`let`** statement. If a tuple has two elements, they can be referenced with the functions `fst` and `snd`, respectively. The elements of a tuple with more than two elements are often referenced with a tuple pattern on the left side of a **`let`** statement. A tuple pattern is simply a sequence of names, one for each element of the tuple, with or without the delimiting parentheses. When a tuple pattern is the left side of a **`let`** construct, it is a multiple assignment. For example, consider the following **`let`** constructs:

```
let tup = (3, 5, 7);;
let a, b, c  = tup;;
```

This assigns `3` to `a`, `5` to `b`, and `7` to `c`.

Tuples are used in Python, ML, and F# to allow functions to return multiple values. In Swift, tuples are passed by value, so they are sometimes used to pass data to a function when the function is not to change that data.

6.9 List Types

Lists were first supported in the first functional programming language, Lisp. They have always been part of the functional languages, but in recent years they have found their way into some imperative languages.

Lists in Scheme and Common Lisp are delimited by parentheses and the elements are not separated by any punctuation. For example,

```
(A B C D)
```

Nested lists have the same form, so we could have

```
(A (B C) D)
```

In this list, `(B C)` is a list nested inside the outer list.

Data and code have the same syntactic form in Lisp and its descendants. If the list `(A B C)` is interpreted as code, it is a call to the function `A` with parameters `B` and `C`.

The fundamental list operations in Scheme are two functions that take lists apart and two that build lists. The `CAR` function returns the first element of its list parameter. For example, consider the following example:

```
(CAR '(A B C))
```

The quote before the parameter list is to prevent the interpreter from considering the list a call to the `A` function with the parameters `B` and `C`, in which case it would interpret it. This call to `CAR` returns `A`.

The `CDR` function returns its parameter list minus its first element. For example, consider the following example:

```
(CDR '(A B C))
```

This function call returns the list `(B C)`.

Common Lisp also has the functions `FIRST` (same as `CAR`), `SECOND`, `...`, `TENTH`, which return the element of their list parameters that is specified by their names.

In Scheme and Common Lisp, new lists are constructed with the `CONS` and `LIST` functions. The function `CONS` takes two parameters and returns a new list with its first parameter as the first element and its second parameter as the remainder of that list. For example, consider the following:

```
(CONS 'A '(B C))
```

This call returns the new list `(A B C)`.

The `LIST` function takes any number of parameters and returns a new list with the parameters as its elements. For example, consider the following call to `LIST`:

```
(LIST 'A 'B '(C D))
```

This call returns the new list `(A B (C D))`.

ML has lists and list operations, although their appearance is not like those of Scheme. Lists are specified in square brackets, with the elements separated by commas, as in the following list of integers:

```
[5, 7, 9]
```

`[]` is the empty list, which could also be specified with `nil`.

The Scheme `CONS` function is implemented as a binary infix operator in ML, represented as `::`. For example,

```
3 :: [5, 7, 9]
```

returns the following new list: `[3, 5, 7, 9]`.

The elements of a list must be of the same type, so the following list would be illegal:

```
[5, 7.3, 9]
```

ML has functions that correspond to Scheme's `CAR` and `CDR`, named `hd` (head) and `tl` (tail). For example,

```
hd [5, 7, 9] is 5
tl [5, 7, 9] is [7, 9]
```

Lists and list operations in Scheme and ML are more fully discussed in Chapter 15.

Lists in F# are related to those of ML with a few notable differences. - Elements of a list in F# are separated by semicolons, rather than the commas of ML. The operations `hd` and `tl` are the same, but they are called as methods of the `List` class, as in `List.hd [1; 3; 5; 7]`, which returns `1`. The `CONS` operation of F# is specified as two colons, as in ML.

Python includes a list data type, which also serves as Python's arrays. Unlike the lists of Scheme, Common Lisp, ML, and F#, the lists of Python are mutable. They can contain any data value or object. A Python list is created with an assignment of a list value to a name. A list value is a sequence of expressions that are separated by commas and delimited with brackets. For example, consider the following statement:

```
myList = [3, 5.8, "grape"]
```

The elements of a list are referenced with subscripts in brackets, as in the following example:

```
x = myList[1]
```

This statement assigns `5.8` to `x`. The elements of a list are indexed starting at zero. List elements also can be updated by assignment. A list element can be deleted with `del`, as in the following statement:

```
del myList[1]
```

This statement removes the second element of `myList`.

Python includes a powerful mechanism for creating arrays called **list comprehensions**. A list comprehension is an idea derived from set notation. It first appeared in the functional programming language Haskell (see

Chapter 15). The mechanics of a list comprehension is that a function is applied to each of the elements of a given array and a new array is constructed from the results. The syntax of a Python list comprehension is as follows:

[expression **for** iterate_var **in** array **if** condition]

Consider the following example:

```
[x * x  for  x  in range(12)  if  x % 3 == 0]
```

The **range** function creates the array `[0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12]`. The conditional filters out all numbers in the array that are not evenly divisible by `3`. Then, the expression squares the remaining numbers. The results of the squaring are collected in an array, which is returned. This list comprehension returns the following array:

```
[0, 9, 36, 81]
```

Slices of lists are also supported in Python.

Haskell's list comprehensions have the following form:

- `[`body `|` qualifiers`]`

For example, consider the following definition of a list:

```
[n * n | n <- [1..10]]
```

This defines a list of the squares of the numbers from `1` to `10`.

F# includes list comprehensions, which in that language can also be used to create arrays. For example, consider the following statement:

```
let myArray = [|for i in 1 .. 5 -> (i * i) |];;
```

This statement creates the array `[1; 4; 9; 16; 25]` and names it `myArray`.

Recall from Section 6.5 that C# and Java support generic heap-dynamic collection classes, `List` and `ArrayList`, respectively. These structures are

actually lists.

6.10 Union Types

A **union** is a type whose variables may store different type values at different times during program execution. As an example of the need for a union type, consider a table of constants for a compiler, which is used to store the constants found in a program being compiled. One field of each table entry is for the value of the constant. Suppose that for a particular language being compiled, the types of constants were integer, floating-point, and Boolean. In terms of table management, it would be convenient if the same location, a table field, could store a value of any of these three types. Then all constant values could be addressed in the same way. The type of such a location is, in a sense, the union of the three value types it can store.

6.10.1 Design Issues

The problem of type checking union types, which is discussed in Section 6.12, is their major design issue.

6.10.2 Discriminated Versus Free Unions

C and C++ provide union constructs in which there is no language support for type checking. In C and C++, the **`union`** construct is used to specify union structures. The unions in these languages are called **free unions**, because programmers are allowed complete freedom from type checking in their use. For example, consider the following C union:

```
union flexType {
 int intEl;
 float  floatEl;
};
union flexType el1;
```

```
float x;
. . .
el1.intEl = 27;
x = el1.floatEl;
```

This last assignment is not type checked, because the system cannot determine the current type of the current value of `el1`, so it assigns the bit string representation of `27` to the **`float`** variable `x`, which, of course, is nonsense.

Type checking of unions requires that each union construct include a type indicator. Such an indicator is called a **tag**, or **discriminant**, and a union with a discriminant is called a **discriminated union**. The first language to provide discriminated unions was ALGOL 68. They are now supported by ML, Haskell, and F#.

6.10.3 Unions in F#

A union is declared in F# with a type statement using OR operators (`|`) to define the components. For example, we could have the following:

```
type intReal =
   | IntValue of int
   | RealValue of float;;
```

In this example, `intReal` is the union type. `IntValue` and `RealValue` are constructors. Values of type `intReal` can be created using the constructors as if they were a function, as in the following examples:7

7. The **`let`** statement is used to assign values to names and to create a static scope; the double semicolons are used to terminate statements when the F# interactive interpreter is being used.

```
let ir1 = IntValue 17;;
let ir2 = RealValue 3.4;;
```

Accessing the value of a union is done with a pattern-matching structure. Pattern matching in F# is specified with the **`match`** reserved word. The general form of the construct is as follows:

- **match** pattern **with**
- | expression_list1−>expression1
- | . . .
- | expression_listn−>expressionn

The pattern can be any data type. The expression list can include wild card characters (_) or be solely a wild card character. For example, consider the following match construct:

```
let a = 7;;
let b = "grape";;
let x = match (a, b) with
     | 4, "apple" -> apple
     | _, "grape" -> grape
     | _ -> fruit;;
```

To display the type of the `intReal` union, the following function could be used:

```
let printType value =
    match value with
        | IntValue value -> printfn "It is an integer"
        | RealValue value -> printfn "It is a float";;
```

The following lines show calls to this function and the output:

```
printType ir1;;
It is an integer
printType ir2;;
It is a float
```

6.10.4 Evaluation

Unions are potentially unsafe constructs in some languages. They are one of the reasons why C and C++ are not strongly typed: These languages do not allow type checking of references to their unions. On the other hand, unions can be safely used, as in their design in ML, Haskell, and F#.

Neither Java nor C# includes unions, which may be reflective of the growing concern for safety in some programming languages.

6.10.5 Implementation of Union Types

Unions are implemented by simply using the same address for every possible variant. Sufficient storage for the largest variant is allocated.

6.11 Pointer and Reference Types

A **pointer** type is one in which the variables have a range of values that consists of memory addresses and a special value, **nil**. The value nil is not a valid address and is used to indicate that a pointer cannot currently be used to reference a memory cell.

Pointers are designed for two distinct kinds of uses. First, pointers provide some of the power of indirect addressing, which is frequently used in assembly language programming. Second, pointers provide a way to manage dynamic storage. A pointer can be used to access a location in an area where storage is dynamically allocated called a **heap**.

Variables that are dynamically allocated from the heap are called **heap--dynamic variables**. They often do not have identifiers associated with them and thus can be referenced only by pointer or reference type variables. - Variables without names are called **anonymous variables**. It is in this latter application area of pointers that the most important design issues arise.

Pointers, unlike arrays and records, are not structured types, although they are defined using a type operator (`*` in C and C++). Furthermore, they are also different from scalar variables because they are used to reference some other variable, rather than being used to store data. These two categories of variables are called **reference types** and **value types**, respectively.

Both kinds of uses of pointers add writability to a language. For example, suppose it is necessary to implement a dynamic structure like a binary tree in a language that does not have pointers or dynamic storage. This would require the programmer to provide and maintain a pool of available tree nodes, which would probably be implemented in parallel arrays. Also, it would be necessary for the programmer to guess the maximum number of required nodes. This is clearly an awkward and error-prone way to deal with binary trees.

Reference variables, which are discussed in Section 6.11.6, are closely related

to pointers.

6.11.1 Design Issues

The primary design issues particular to pointers are the following:

- What are the scope and lifetime of a pointer variable?
- What is the lifetime of a heap-dynamic variable (the value a pointer references)?
- Are pointers restricted as to the type of value to which they can point?
- Are pointers used for dynamic storage management, indirect addressing, or both?
- Should the language support pointer types, reference types, or both?

6.11.2 Pointer Operations

Languages that provide a pointer type usually include two fundamental pointer operations: assignment and dereferencing. The first operation sets a pointer variable’s value to some useful address. If pointer variables are used only to manage dynamic storage, then the allocation mechanism, whether by operator or built-in subprogram, serves to initialize the pointer variable. If pointers are used for indirect addressing to variables that are not heap dynamic, then there must be an explicit operator or built-in subprogram for fetching the address of a variable, which can then be assigned to the pointer variable.

An occurrence of a pointer variable in an expression can be interpreted in two distinct ways. First, it could be interpreted as a reference to the contents of the memory cell to which it is bound, which in the case of a pointer is an address. This is exactly how a nonpointer variable in an expression would be interpreted, although in that case its value likely would not be an address.

However, the pointer also could be interpreted as a reference to the value in the memory cell pointed to by the memory cell to which the pointer variable is bound. In this case, the pointer is interpreted as an indirect reference. The former case is a normal pointer reference; the latter is the result of **dereferencing** the pointer. Dereferencing, which takes a reference through one level of indirection, is the second fundamental pointer operation.

Dereferencing of pointers can be either explicit or implicit. In many contemporary languages, it occurs only when explicitly specified. In C++, it is explicitly specified with the asterisk (`*`) as a prefix unary operator. Consider the following example of dereferencing: If `ptr` is a pointer variable with the value 7080 and the cell whose address is 7080 has the value 206, then the assignment

```
j = *ptr
```

sets `j` to 206. This process is shown in Figure 6.8.

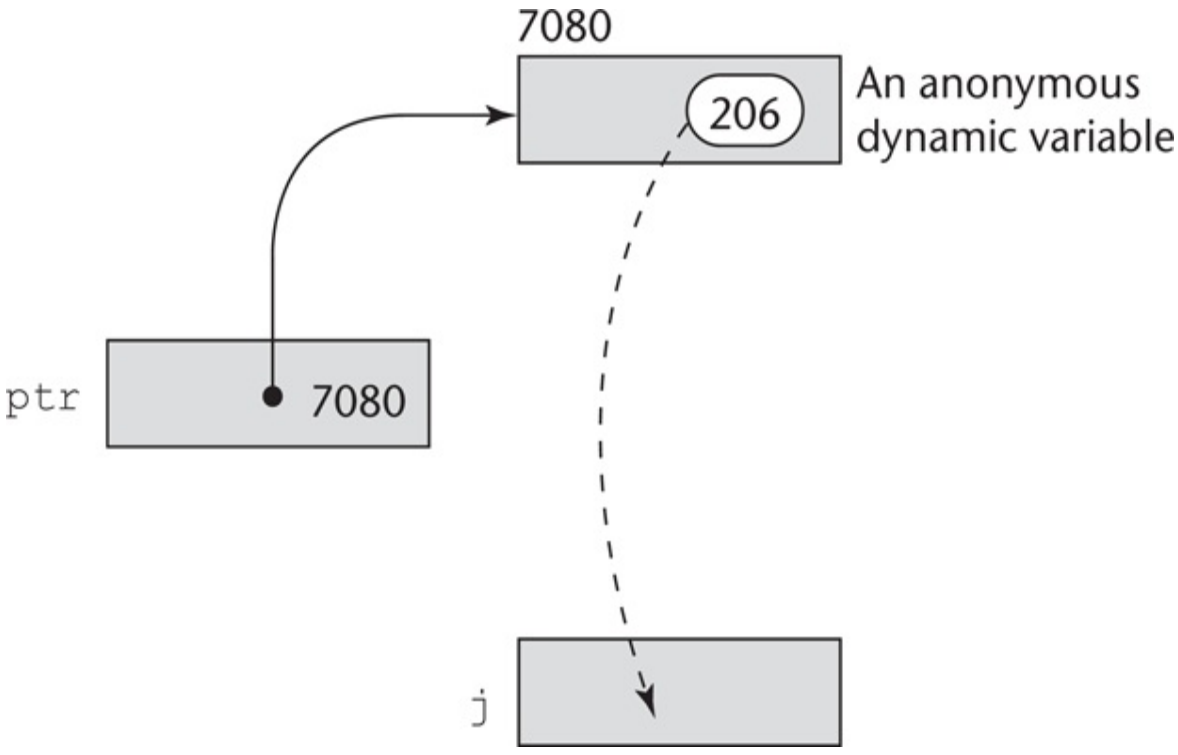

Figure 6.8 The assignment -

operation `j = *ptr`

Figure 6.8 Full Alternative Text

When pointers point to records, the syntax of the references to the fields of these records varies among languages. In C and C++, there are two ways a pointer to a record can be used to reference a field in that record. If a pointer variable `p` points to a record with a field named `age`, `(*p).age` can be used to refer to that field. The operator `->`, when used between a pointer to a struct and a field of that struct, combines dereferencing and field reference. For example, the expression `p -> age` is equivalent to `(*p).age`.

Languages that provide pointers for the management of a heap must include an explicit allocation operation. Allocation is sometimes specified with a subprogram, such as `malloc` in C. In languages that support object-oriented programming, allocation of heap objects is often specified with the **`new`** operator. C++, which does not provide implicit deallocation, uses **`delete`** as its deallocation operator.

6.11.3 Pointer Problems

The first high-level programming language to include pointer variables was PL/I, in which pointers could be used to refer to both heap-dynamic variables and other program variables. The pointers of PL/I were highly flexible, but their use could lead to several kinds of programming errors. Some of the problems of PL/I pointers are also present in the pointers of subsequent languages. Some recent languages, such as Java, have replaced pointers completely with reference types, which, along with implicit deallocation, minimize the primary problems with pointers. A reference type is really only a pointer with restricted operations.

6.11.3.1 Dangling Pointers

A **dangling pointer**, or **dangling reference**, is a pointer that contains the address of a heap-dynamic variable that has been deallocated. Dangling pointers are dangerous for several reasons. First, the location being pointed to may have been reallocated to some new heap-dynamic variable. If the new variable is not the same type as the old one, type checks of uses of the dangling pointer are invalid. Even if the new dynamic variable is the same type, its new value will have no relationship to the old pointer's dereferenced value. Furthermore, if the dangling pointer is used to change the heap-dynamic variable, the value of the new heap-dynamic variable will be destroyed. Finally, it is possible that the location now is being temporarily used by the storage management system, possibly as a pointer in a chain of available blocks of storage, thereby allowing a change to the location to cause the storage manager to fail.

The following sequence of operations creates a dangling pointer in many languages:

1. A new heap-dynamic variable is created and pointer `p1` is set to point to it.

2. Pointer `p2` is assigned `p1`'s value.

3. The heap-dynamic variable pointed to by `p1` is explicitly deallocated (possibly setting `p1` to `nil`), but `p2` is not changed by the operation. `p2` is now a dangling pointer. If the deallocation operation did not change `p1`, both `p1` and `p2` would be dangling. (Of course, this is a problem of aliasing—`p1` and `p2` are aliases.)

For example, in C++ we could have the following:

```
int * arrayPtr1;
int * arrayPtr2 = new int[100];
arrayPtr1 = arrayPtr2;
delete [] arrayPtr2;
// Now, arrayPtr1 is dangling, because the heap storage
// to which it was pointing has been deallocated.
```

In C++, both `arrayPtr1` and `arrayPtr2` are now dangling pointers, because the C++ **`delete`** operator has no effect on the value of its operand pointer. In

C++, it is common (and safe) to follow a **`delete`** operator with an assignment of zero, which represents null, to the pointer whose pointed-to value has been deallocated.

Notice that the explicit deallocation of dynamic variables is the cause of dangling pointers.

history note

Pascal included an explicit deallocate operator: dispose. Because of the problem of dangling pointers caused by dispose, some Pascal implementations simply ignored dispose when it appeared in a program. Although this effectively prevents dangling pointers, it also disallows the reuse of heap storage that the program no longer needs. Recall that Pascal initially was designed as a teaching language, rather than as an industrial tool.

6.11.3.2 Lost Heap-Dynamic Variables

A **lost heap-dynamic variable** is an allocated heap-dynamic variable that is no longer accessible to the user program. Such variables are often called **garbage**, because they are not useful for their original purpose, and they also cannot be reallocated for some new use in the program. Lost heap-dynamic variables are most often created by the following sequence of operations:

1. Pointer `p1` is set to point to a newly created heap-dynamic variable.

2. `p1` is later set to point to another newly created heap-dynamic variable.

The first heap-dynamic variable is now inaccessible, or lost. This is sometimes called **memory leakage**. Memory leakage is a problem, regardless of whether the language uses implicit or explicit deallocation. In the following sections, we investigate how language designers have dealt with the problems of dangling pointers and lost heap-dynamic variables.

6.11.4 Pointers in C and C++

In C and C++, pointers can be used in the same ways as addresses are used in assembly languages. This means they are extremely flexible but must be used with great care. This design offers no solutions to the dangling pointer or lost heap-dynamic variable problems. However, the fact that pointer arithmetic is possible in C and C++ makes their pointers more interesting than those of the other programming languages.

C and C++ pointers can point at any variable, regardless of where it is allocated. In fact, they can point anywhere in memory, whether there is a variable there or not, which is one of the dangers of such pointers.

In C and C++, the asterisk (`*`) denotes the dereferencing operation and the ampersand (`&`) denotes the operator for producing the address of a variable. For example, consider the following code:

```
int *ptr;
int count, init;
. . .
ptr = &init;
count = *ptr;
```

The assignment to the variable `ptr` sets it to the address of `init`. The assignment to `count` dereferences `ptr` to produce the value at `init`, which is then assigned to `count`. So, the effect of the two assignment statements is to assign the value of `init` to `count`. Notice that the declaration of a pointer specifies its domain type.

Pointers can be assigned the address value of any variable of the correct domain type, or they can be assigned the constant zero, which is used for `nil`.

Pointer arithmetic is also possible in some restricted forms. For example, if `ptr` is a pointer variable that is declared to point at some variable of some data type, then

```
ptr + index
```

is a legal expression. The semantics of such an expression is as follows. Instead of simply adding the value of `index` to `ptr`, the value of `index` is first scaled by the size of the memory cell (in memory units) to which `ptr` is pointing (its base type). For example, if `ptr` points to a memory cell for a type that is four memory units in size, then `index` is multiplied by 4, and the result is added to `ptr`. The primary purpose of this sort of address arithmetic is array manipulation. The following discussion is related to single--dimensioned arrays only.

In C and C++, all arrays use zero as the lower bound of their subscript ranges, and array names without subscripts always refer to the address of the first element. Consider the following declarations:

```
int list [10];
int *ptr;
```

Now consider the assignment

```
ptr = list;
```

This assigns the address of `list[0]` to `ptr`. Given this assignment, the following are true:

- `*(ptr + 1)` is equivalent to `list[1]`.
- `*(ptr + index)` is equivalent to `list[index]`.
- `ptr[index]` is equivalent to `list[index]`.

It is clear from these statements that the pointer operations include the same scaling that is used in indexing operations. Furthermore, pointers to arrays can be indexed as if they were array names.

Pointers in C and C++ can point to functions. This feature is used to pass functions as parameters to other functions. Pointers are also used for parameter passing, as discussed in Chapter 9.

C and C++ include pointers of type **`void *`**, which can point at values of any type. In effect they are generic pointers. However, type checking is not a

problem with **`void *`** pointers, because these languages disallow dereferencing them. One common use of **`void *`** pointers is as the types of parameters of functions that operate on memory. For example, suppose we wanted a function to move a sequence of bytes of data from one place in memory to another. It would be most general if it could be passed two pointers of any type. This would be legal if the corresponding formal parameters in the function were **`void *`** type. The function could then convert them to **`char *`** type and do the operation, regardless of what type pointers were sent as actual parameters.

6.11.5 Reference Types

A **reference type** variable is similar to a pointer, with one important and fundamental difference: A pointer refers to an address in memory, while a reference refers to an object or a value in memory. As a result, although it is natural to perform arithmetic on addresses, it is not sensible to do arithmetic on references.

C++ includes a special kind of reference type that is used primarily for the formal parameters in function definitions. A C++ reference type variable is a constant pointer that is always implicitly dereferenced. Because a C++ reference type variable is a constant, it must be initialized with the address of some variable in its definition, and after initialization a reference type variable can never be set to reference any other variable. The implicit dereference prevents assignment to the address value of a reference variable.

Reference type variables are specified in definitions by preceding their names with ampersands (`&`). For example,

```
int result = 0;
 int &ref_result = result;
. . .
ref_result = 100;
```

In this code segment, `result` and `ref_result` are aliases.

When used as formal parameters in function definitions, C++ reference types

provide for two-way communication between the caller function and the called function. This is not possible with nonpointer primitive parameter types, because C++ parameters are passed by value. Passing a pointer as a parameter accomplishes the same two-way communication, but pointer formal parameters require explicit dereferencing, making the code less readable and less safe. Reference parameters are referenced in the called function exactly as are other parameters. The calling function need not specify that a parameter whose corresponding formal parameter is a reference type is anything unusual. The compiler passes addresses, rather than values, to reference parameters.

In their quest for increased safety over C++, the designers of Java removed C++-style pointers altogether. Unlike C++ reference variables, Java reference variables can be assigned to refer to different class instances; they are not constants. All Java class instances are referenced by reference variables. That is, in fact, the only use of reference variables in Java. These issues are discussed further in Chapter 12.

In the following, `String` is a standard Java class:

```
String str1;
. . .
str1 = "This is a Java literal string";
```

In this code, `str1` is defined to be a reference to a `String` class instance or object. It is initially set to null. The subsequent assignment sets `str1` to reference the `String` object, `"This is a Java literal string"`.

Because Java class instances are implicitly deallocated (there is no explicit deallocation operator), there cannot be dangling references in Java.

C# includes both the references of Java and the pointers of C++. However, the use of pointers is strongly discouraged. In fact, any subprogram that uses pointers must include the **`unsafe`** modifier. Note that although objects pointed to by references are implicitly deallocated, that is not true for objects pointed to by pointers. Pointers were included in C# primarily to allow C# programs to interoperate with C and C++ code.

All variables in the object-oriented languages Smalltalk, Python, and Ruby

are references. They are always implicitly dereferenced. Furthermore, the direct values of these variables cannot be accessed.

6.11.6 Evaluation

The problems of dangling pointers and garbage have already been discussed at length. The problems of heap management are discussed in Section 6.11.7.3.

Pointers have been compared with the goto. The goto statement widens the range of statements that can be executed next. Pointer variables widen the range of memory cells that can be referenced by a variable. Perhaps the most damning statement about pointers was made by Hoare (1973): “Their introduction into high-level languages has been a step backward from which we may never recover.”

On the other hand, pointers are essential in some kinds of programming applications. For example, pointers are necessary to write device drivers, in which specific absolute addresses must be accessed.

The references of Java and C# provide some of the flexibility and the capabilities of pointers, without the hazards. It remains to be seen whether programmers will be willing to trade the full power of C and C++ pointers for the greater safety of references. The extent to which C# programs use pointers will be one measure of this.

6.11.7 Implementation of Pointer and Reference Types

In most languages, pointers are used in heap management. The same is true for Java and C# references, as well as the variables in Smalltalk and Ruby, so we cannot treat pointers and references separately. First, we briefly describe how pointers and references are represented internally. We then discuss two possible solutions to the dangling pointer problem. Finally, we describe the

major problems with heap-management techniques.

6.11.7.1 Representations of Pointers and References

In most larger computers, pointers and references are single values stored in memory cells. However, in early microcomputers based on Intel microprocessors, addresses have two parts: a segment and an offset. So, pointers and references are implemented in these systems as pairs of 16-bit cells, one for each of the two parts of an address.

6.11.7.2 Solutions to the Dangling-Pointer Problem

There have been several proposed solutions to the dangling-pointer problem. Among these are **tombstones** (Lomet, 1975), in which every heap-dynamic variable includes a special cell, called a tombstone, that is itself a pointer to the heap-dynamic variable. The actual pointer variable points only at tombstones and never to heap-dynamic variables. When a heap-dynamic variable is deallocated, the tombstone remains but is set to nil, indicating that the heap-dynamic variable no longer exists. This approach prevents a pointer from ever pointing to a deallocated variable. Any reference to any pointer that points to a `nil` tombstone can be detected as an error.

Tombstones are costly in both time and space. Because tombstones are never deallocated, their storage is never reclaimed. Every access to a heap-dynamic variable through a tombstone requires one more level of indirection, which requires an additional machine cycle on most computers. Apparently none of the designers of the more popular languages have found the additional safety to be worth this additional cost, because no widely used language uses tombstones.

An alternative to tombstones is the **locks-and-keys approach** used in the implementation of UW-Pascal (Fischer and LeBlanc, 1977, 1980). In this compiler, pointer values are represented as ordered pairs (key, address), where the key is an integer value. Heap-dynamic variables are represented as the storage for the variable plus a header cell that stores an integer lock value. When a heap-dynamic variable is allocated, a lock value is created and placed both in the lock cell of the heap-dynamic variable and in the key cell of the pointer that is specified in the call to **`new`**. Every access to the dereferenced pointer compares the key value of the pointer to the lock value in the heap-dynamic variable. If they match, the access is legal; otherwise the access is treated as a run-time error. Any copies of the pointer value to other pointers must copy the key value. Therefore, any number of pointers can reference a given heap-dynamic variable. When a heap-dynamic variable is deallocated with **`dispose`**, its lock value is cleared to an illegal lock value. Then, if a pointer other than the one specified in the **`dispose`** is dereferenced, its address value will still be intact, but its key value will no longer match the lock, so the access will not be allowed.

Of course, the best solution to the dangling-pointer problem is to take deallocation of heap-dynamic variables out of the hands of programmers. If programs cannot explicitly deallocate heap-dynamic variables, there will be no dangling pointers. To do this, the run-time system must implicitly deallocate heap-dynamic variables when they are no longer useful. Lisp systems have always done this. Both Java and C# also use this approach for their reference variables. Recall that C#'s pointers do not include implicit deallocation.

6.11.7.3 Heap Management

Heap management can be a very complex run-time process. We examine the process in two separate situations: one in which all heap storage is allocated and deallocated in units of a single size, and one in which variable-size segments are allocated and deallocated. Note that for deallocation, we discuss only implicit approaches. Our discussion will be brief and far from comprehensive, since a thorough analysis of these processes and their associated problems is not so much a language design issue as it is an

implementation issue.

Single-Size Cells

The simplest situation is when all allocation and deallocation is of single-size cells. It is further simplified when every cell already contains a pointer. This is the scenario of many implementations of Lisp, where the problems of dynamic storage allocation were first encountered on a large scale. All Lisp programs and most Lisp data consist of cells in linked lists.

In a single-size allocation heap, all available cells are linked together using the pointers in the cells, forming a list of available space. Allocation is a - simple matter of taking the required number of cells from this list when they are needed. Deallocation is a much more complex process. A heap-dynamic - variable can be pointed to by more than one pointer, making it difficult to determine when the variable is no longer useful to the program. Simply because one pointer is disconnected from a cell obviously does not make it garbage; there could be several other pointers still pointing to the cell.

In Lisp, several of the most frequent operations in programs create collections of cells that are no longer accessible to the program and therefore should be deallocated (put back on the list of available space). One of the fundamental design goals of Lisp was to ensure that reclamation of unused cells would not be the task of the programmer but rather that of the run-time system. This goal left Lisp implementors with the fundamental design question: When should deallocation be performed?

There are several different approaches to garbage collection. The two most common traditional techniques are in some ways opposite processes. These are named **reference counters**, in which reclamation is incremental and is done when inaccessible cells are created, and **mark-sweep**, in which reclamation occurs only when the list of available space becomes empty. These two methods are sometimes called the **eager approach** and the **lazy approach**, respectively. Many variations of these two approaches have been developed. In this section, however, we discuss only the basic processes.

The reference counter method of storage reclamation accomplishes its goal by maintaining in every cell a counter that stores the number of pointers that are currently pointing at the cell. Embedded in the decrement operation for the reference counters, which occurs when a pointer is disconnected from the cell, is a check for a zero value. If the reference counter reaches zero, it means that no program pointers are pointing at the cell, and it has thus become garbage and can be returned to the list of available space.

There are three distinct problems with the reference counter method. First, if storage cells are relatively small, the space required for the counters is significant. Second, some execution time is obviously required to maintain the counter values. Every time a pointer value is changed, the cell to which it was pointing must have its counter decremented, and the cell to which it is now pointing must have its counter incremented. In a language like Lisp, in which nearly every action involves changing pointers, that can be a significant portion of the total execution time of a program. Of course, if pointer changes are not too frequent, this is not a problem. Some of the inefficiency of reference counters can be eliminated by an approach named **deferred reference counting**, which avoids reference counters for some pointers. The third problem is that complications arise when a collection of cells is connected circularly. The problem here is that each cell in the circular list has a reference counter value of at least 1, which prevents it from being collected and placed back on the list of available space. A solution to this problem can be found in Friedman and Wise (1979).

The advantage of the reference counter approach is that it is intrinsically incremental. Its actions are interleaved with those of the application, so it never causes significant delays in the execution of the application.

The original mark-sweep process of garbage collection operates as follows: The run-time system allocates storage cells as requested and disconnects pointers from cells as necessary, without regard for storage reclamation (allowing garbage to accumulate), until it has allocated all available cells. At this point, a mark-sweep process is begun to gather all the garbage left floating around in the heap. To facilitate the process, every heap cell has an extra indicator bit or field that is used by the collection algorithm.

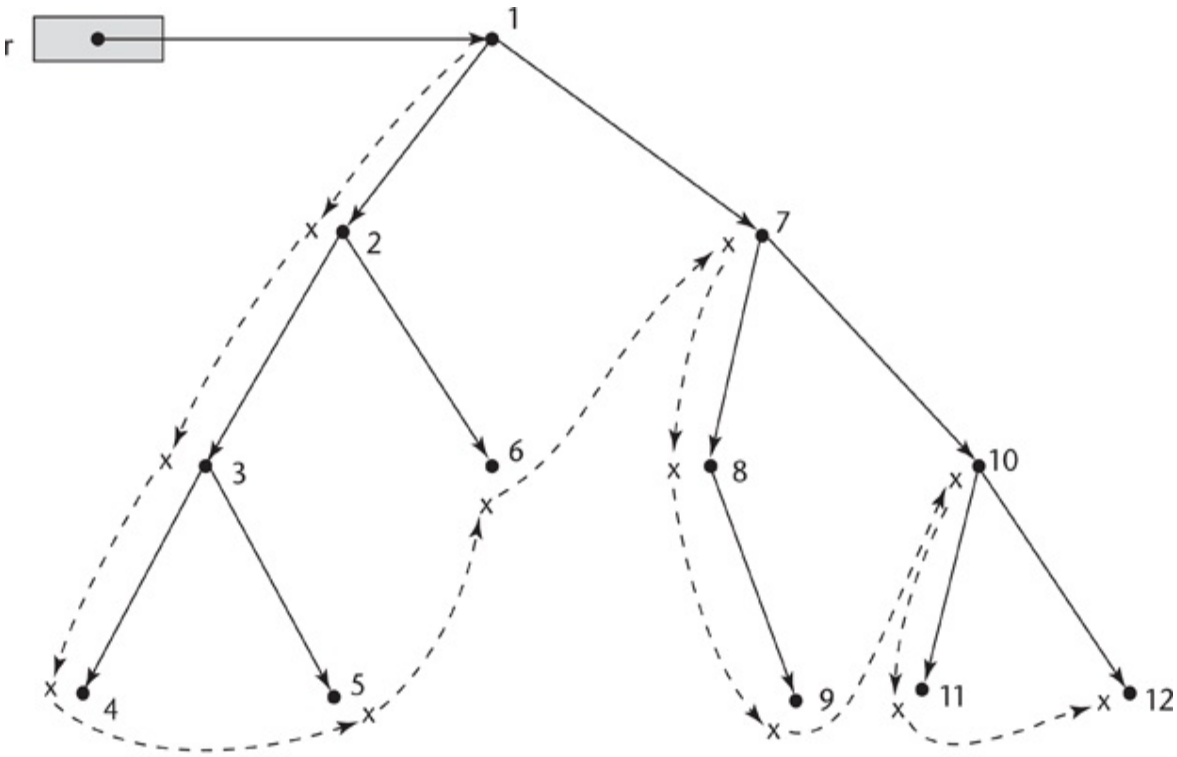
The mark-sweep process consists of three distinct phases. First, all cells in

the heap have their indicators set to indicate they are garbage. This is, of course, a correct assumption for only some of the cells. The second part, called the marking phase, is the most difficult. Every pointer in the program is traced into the heap, and all reachable cells are marked as not being garbage. After this, the third phase, called the sweep phase, is executed: All cells in the heap that have not been specifically marked as still being used are returned to the list of available space.

To illustrate the flavor of algorithms used to mark the cells that are currently in use, we provide the following simple version of a marking algorithm. We assume that all heap-dynamic variables, or heap cells, consist of an information part; a part for the mark, named `marker`; and two pointers named `llink` and `rlink`. These cells are used to build directed graphs with at most two edges leading from any node. The marking algorithm traverses all spanning trees of the graphs, marking all cells that are found. Like other graph traversals, the marking algorithm uses recursion.

```
for every pointer r  do
    mark(r)
void mark(void  * ptr) {
    if (ptr != 0)
      if (*ptr.marker is not marked) {
        set *ptr.marker
        mark(*ptr.llink)
        mark(*ptr.rlink)
       }
}
```

An example of the actions of this procedure on a given graph is shown in Figure 6.9. This simple marking algorithm requires a great deal of storage (for stack space to support recursion). A marking process that does not require additional stack space was developed by Schorr and Waite (1967). Their method reverses pointers as it traces out linked structures. Then, when the end of a list is reached, the process can follow the pointers back out of the structure.



Dashed lines show the order of node_marking

Figure 6.9 An example of the actions of the marking algorithm

Figure 6.9 Full Alternative Text

The most serious problem with the original version of mark-sweep was that it was done too infrequently—only when a program had used all or nearly all of the heap storage. Mark-sweep in that situation takes a good deal of time, because most of the cells must be traced and marked as being currently used. This causes a significant delay in the progress of the application. Furthermore, the process may yield only a small number of cells that can be placed on the list of available space. This problem has been addressed in a

variety of improvements. For example, **incremental mark-sweep** garbage collection occurs more frequently, long before memory is exhausted, making the process more effective in terms of the amount of storage that is reclaimed. Also, the time required for each run of the process is obviously shorter, thus reducing the delay in application execution. Another alternative is to perform the mark-sweep process on parts, rather than all of the memory associated with the application, at different times. This provides the same kinds of improvements as incremental mark-sweep.

Both the marking algorithms for the mark-sweep method and the processes required by the reference counter method can be made more efficient by use of the pointer rotation and slide operations that are described by Suzuki (1982).

Variable-Size Cells

Managing a heap from which variable-size cells[8] are allocated has all the difficulties of managing one for single-size cells, but also has additional problems. Unfortunately, variable-size cells are required by most programming languages. The additional problems posed by variable-size cell management depend on the method used. If mark-sweep is used, the following additional problems occur:

8. The cells have variable sizes because these are abstract cells, which store the values of variables, regardless of their types. Furthermore, a variable could be a structured type.

- The initial setting of the indicators of all cells in the heap to indicate that they are garbage is difficult. Because the cells are different sizes, scanning them is a problem. One solution is to require each cell to have the cell size as its first field. Then the scanning can be done, although it takes slightly more space and somewhat more time than its counterpart for fixed-size cells.

- The marking process is nontrivial. How can a chain be followed from a pointer if there is no predefined location for the pointer in the pointed-to

cell? Cells that do not contain pointers at all are also a problem. Adding an internal pointer to each cell, which is maintained in the background by the run-time system, will work. However, this background maintenance processing adds both space and execution time overhead to the cost of running the program.

- Maintaining the list of available space is another source of overhead. The list can begin with a single cell consisting of all available space. Requests for segments simply reduce the size of this block. Reclaimed cells are added to the list. The problem is that before long, the list becomes a long list of various-size segments, or blocks. This slows allocation because requests cause the list to be searched for sufficiently large blocks. Eventually, the list may consist of a large number of very small blocks, which are not large enough for most requests. At this point, adjacent blocks may need to be collapsed into larger blocks. Alternatives to using the first sufficiently large block on the list can shorten the search but require the list to be ordered by block size. In either case, maintaining the list is additional overhead.

If reference counters are used, the first two problems are avoided, but the available-space list-maintenance problem remains.

For a comprehensive study of memory management problems, see Wilson (2005).

6.12 Optional Types

There are situations in programming when there is a need to be able to indicate that a variable does not currently have a value. Some older languages use zero as a nonvalue for numeric variables. This approach has the disadvantage of not being able to distinguish between when the variable is supposed to have the zero value and when the zero indicates that it has no value. Some newer languages provide types that can have a normal value or a special value to indicate that their variables have no value. Variables that have this capability are called **optional types**. Optional types are now directly supported in C#, F#, and Swift, among others.

C# has two categories of variables, value and reference types. Reference types, which are classes, are optional types by their nature. The **`null`** value indicates that a reference type has no value. Value types, which are all struct types, can be declared to be optional types, which allows them to have the value **`null`**. A variable is declared to be an optional type by following its type name with a question mark `(?)`, as in

```
int? x;
```

To determine whether a variable has a normal value, it can be tested against **`null`**, as in

```
int? x;
. . .
if(x == null)
   Console.WriteLine("x has no value");
else
   Console.WriteLine("The value of x is: {0}", x);
```

Swift's optional types are similar to those of C#, except that the nonvalue is named **`nil`**, instead of **`null`**. The Swift version of the above code is:

```
var Int? x;
. . .
if x == nil
   print("x has no value")
```

```
else
   print("The value of x is: \(x)")
```

6.13 Type Checking

For our discussion of type checking, the concept of operands and operators is generalized to include subprograms and assignment statements. Subprograms will be thought of as operators whose operands are their parameters. The assignment symbol will be thought of as a binary operator, with its target variable and its expression being the operands.

Type checking is the activity of ensuring that the operands of an operator are of compatible types. A **compatible** type is one that either is legal for the operator or is allowed under language rules to be implicitly converted by compiler-generated code (or the interpreter) to a legal type. This automatic conversion is called a **coercion**. For example, if an `int` variable and a `float` variable are added in Java, the value of the `int` variable is coerced to `float` and a floating-point add is done.

A **type error** is the application of an operator to an operand of an inappropriate type. For example, in the original version of C, if an `int` value was passed to a function that expected a `float` value, a type error would occur (because compilers for that language did not check the types of parameters).

If all bindings of variables to types are static in a language, then type checking can nearly always be done statically. Dynamic type binding requires type checking at run time, which is called **dynamic type checking**.

Some languages, such as JavaScript and PHP, because of their dynamic type binding, allow only dynamic type checking. It is better to detect errors at compile time than at run time, because the earlier correction is usually less costly. The penalty for static checking is reduced programmer flexibility. Fewer shortcuts and tricks are possible. Such techniques, though, are now generally recognized to be error prone and detrimental to readability.

Type checking is complicated when a language allows a memory cell to store values of different types at different times during execution. Such memory

cells can be created with C and C++ unions and the discriminated unions of ML, Haskell, and F#. In these cases, type checking, if done, must be dynamic and requires the run-time system to maintain the type of the current value of such memory cells. So, even though all variables are statically bound to types in languages such as C++, not all type errors can be detected by static type checking.

6.14 Strong Typing

One of the ideas in language design that became prominent in the so-called structured-programming revolution of the 1970s was **strong typing**. Strong typing is widely acknowledged as being a highly valuable language characteristic. Unfortunately, it is often loosely defined, and it is sometimes used in computing literature without being defined at all.

A programming language is **strongly typed** if type errors are always detected. This requires that the types of all operands can be determined, either at compile time or at run time. The importance of strong typing lies in its ability to detect all misuses of variables that result in type errors. A strongly typed language also allows the detection, at run time, of uses of the incorrect type values in variables that can store values of more than one type.

C and C++ are not strongly typed languages because both include union types, which are not type checked.

ML is strongly typed, even though the types of some function parameters may not be known at compile time. F# is strongly typed.

Java and C#, although they are based on C++, are nearly strongly typed. Types can be explicitly cast, which could result in a type error. However, there are no implicit ways type errors can go undetected.

The coercion rules of a language have an important effect on the value of type checking. For example, expressions are strongly typed in Java. However, an arithmetic operator with one floating-point operand and one integer operand is legal. The value of the integer operand is coerced to floating-point, and a floating-point operation takes place. This is what is usually intended by the programmer. However, the coercion also results in a loss of one of the benefits of strong typing—error detection. For example, suppose a program had the `int` variables `a` and `b` and the `float` variable `d`. Now, if a programmer meant to type `a + b`, but mistakenly typed `a + d`, the error would not be detected by the compiler. The value of `a` would simply be

coerced to `float`. So, the value of strong typing is weakened by coercion. Languages with a great deal of coercion, like C, and C++, are less reliable than those with no coercion, such as ML and F#. Java and C# have half as many assignment type coercions as C++, so their error detection is better than that of C++, but still not nearly as effective as that of ML and F#. The issue of coercion is examined in detail in Chapter 7.

6.15 Type Equivalence

The idea of type compatibility was defined when the issue of type checking was introduced. The compatibility rules dictate the types of operands that are acceptable for each of the operators and thereby specify the possible type errors of the language.9 The rules are called compatibility because in some cases the type of an operand can be implicitly converted by the compiler or run-time system to make it acceptable for the operator.

9. Type compatibility is also an issue in the relationship between the actual parameters in a subprogram call and the formal parameters of the subprogram definition. This issue is discussed in Chapter 9.

The type compatibility rules are simple and rigid for the predefined scalar types. However, in the cases of structured types, such as arrays and records and some user-defined types, the rules are more complex. Coercion of these types is rare, so the issue is not type compatibility, but type equivalence. That is, two types are **equivalent** if an operand of one type in an expression can be substituted for one of the other type, without coercion. Type equivalence is a strict form of type compatibility—compatibility without coercion. The central issue here is how type equivalence is defined.

The design of the type equivalence rules of a language is important, because it influences the design of the data types and the operations provided for values of those types. With the types discussed here, there are very few predefined operations. Perhaps the most important result of two variables being of equivalent types is that either one can have its value assigned to the other.

There are two approaches to defining type equivalence: name type equivalence and structure type equivalence. **Name type equivalence** means that two variables have equivalent types if they are defined either in the same declaration or in declarations that use the same type name. **Structure type equivalence** means that two variables have equivalent types if their types have identical structures. There are some variations of these two approaches,

and many languages use combinations of them.

Name type equivalence is easy to implement but is more restrictive. Under a strict interpretation, a variable whose type is a subrange of the integers would not be equivalent to an integer type variable. For example, supposing Ada used strict name type equivalence, consider the following Ada code:

```
type Indextype is 1..100;
count : Integer;
index : Indextype;
```

The types of the variables `count` and `index` would not be equivalent; `count` could not be assigned to `index` or vice versa.

Another problem with name type equivalence arises when a structured or user-defined type is passed among subprograms through parameters. Such a type must be defined only once, globally. A subprogram cannot state the type of such formal parameters in local terms. This was the case with the original version of Pascal.

Note that to use name type equivalence, all types must have names. Most languages allow users to define types that are anonymous—they do not have names. For a language to use name type equivalence, such types must implicitly be given internal names by the compiler.

Structure type equivalence is more flexible than name type equivalence, but it is more difficult to implement. Under name type equivalence, only the two type names must be compared to determine equivalence. Under structure type equivalence, however, the entire structures of the two types must be compared. This comparison is not always simple. (Consider a data structure that refers to its own type, such as a linked list.) Other questions can also arise. For example, are two record (or **`struct`**) types equivalent if they have the same structure but different field names? Are two single-dimensioned array types in a language that allows lower bounds of array subscript ranges to be set in their declarations equivalent if they have the same element type but have subscript ranges of `0..10` and `1..11`? Are two enumeration types equivalent if they have the same number of components but spell the literals differently?

Another difficulty with structure type equivalence is that it disallows differentiating between types with the same structure. For example, consider the following Ada-like declarations:

```
type Celsius = Float;
     Fahrenheit = Float;
```

The types of variables of these two types are considered equivalent under structure type equivalence, allowing them to be mixed in expressions, which is surely undesirable in this case, considering the difference indicated by the type's names. In general, types with different names are likely to be abstractions of different categories of problem values and should not be considered equivalent.

Ada uses a restrictive form of name type equivalence but provides two type constructs, subtypes and derived types, that avoid the problems associated with name type equivalence. A **derived type** is a new type that is based on some previously defined type with which it is not equivalent, although it may have identical structure. Derived types inherit all the properties of their parent types. Consider the following example:

```
type Celsius is new Float;
type Fahrenheit is new Float;
```

The types of variables of these two derived types are not equivalent, although their structures are identical. Furthermore, variables of neither type is type equivalent with any other floating-point type. Literals are exempt from the rule. A literal such as `3.0` has the type universal real and is type equivalent to any floating-point type. Derived types can also include range constraints on the parent type, while still inheriting all of the parent's operations.

An Ada **subtype** is a possibly range-constrained version of an existing type. A subtype is type equivalent with its parent type. For example, consider the following declaration:

```
subtype Small_type is Integer range 0..99;
```

The type `Small_type` is equivalent to the type `Integer`.

Note that Ada's derived types are very different from Ada's subrange types. For example, consider the following type declarations:

```
type Derived_Small_Int is new Integer range 1..100;
subtype Subrange_Small_Int is Integer range 1..100;
```

Variables of both types, `Derived_Small_Int` and `Subrange_Small_Int`, have the same range of legal values and both inherit the operations of `Integer`. However, variables of type `Derived_Small_Int` are not compatible with any `Integer` type. On the other hand, variables of type `Subrange_Small_Int` are compatible with variables and constants of `Integer` type and any subtype of `Integer`.

For variables of an Ada unconstrained array type, structure type equivalence is used. For example, consider the following type declaration and two object declarations:

```
type Vector is array (Integer range <>) of Integer;
Vector_1: Vector (1..10);
Vector_2: Vector (11..20);
```

The types of these two objects are equivalent, even though they have different names and different subscript ranges, because for objects of unconstrained array types, structure type equivalence rather than name type equivalence is used. Because both types have 10 elements and the elements of both are of type `Integer`, they are type equivalent.

For constrained anonymous types, Ada uses a highly restrictive form of name type equivalence. Consider the following Ada declarations of constrained anonymous types:

```
A : array (1..10) of Integer;
```

In this case, `A` has an anonymous but unique type assigned by the compiler and unavailable to the program. If we also had

```
B : array (1..10) of Integer;
```

`A` and `B` would be of anonymous but distinct and not equivalent types, though they are structurally identical. The multiple declaration

```
C, D : array (1..10) of Integer;
```

creates two anonymous types, one for `C` and one for `D`, which are not equivalent. This declaration is actually treated as if it were the following two declarations:

```
C : array (1..10) of Integer;
D : array (1..10) of Integer;
```

Note that Ada's form of name type equivalence is more restrictive than the name type equivalence that is defined at the beginning of this section. If we had written instead

```
type List_10 is array (1..10) of Integer;
C, D : List_10;
```

then the types of `C` and `D` would be equivalent.

Name type equivalence works well for Ada, in part because all types, except anonymous arrays, are required to have type names (and anonymous types are given internal names by the compiler).

Type equivalence rules for Ada are more rigid than those for languages that have many coercions among types. For example, the two operands of an addition operator in Java can have virtually any combination of numeric types in the language. One of the operands will simply be coerced to the type of the other. But in Ada, there are no coercions of the operands of an arithmetic operator.

C uses both name and structure type equivalence. Every **`struct`**, **`enum`**, and **`union`** declaration creates a new type that is not equivalent to any other type. So, name type equivalence is used for structure, enumeration, and union types. Other nonscalar types use structure type equivalence. Array types are equivalent if they have the same type components. Also, if an array type has a constant size, it is equivalent either to other arrays with the same constant size or to with those without a constant size. Note that **`typedef`** in C and C++ does not introduce a new type; it simply defines a new name for an existing type. So, any type defined with **`typedef`** is type equivalent to its parent type. One exception to C using name type equivalence for structures,

enumerations, and unions is if two structures, enumerations, or unions are defined in different files, in which case structural type equivalence is used. This is a loophole in the name type equivalence rule to allow equivalence of structures, enumerations, and unions that are defined in different files.

C++ is like C except there is no exception for structures and unions defined in different files.

In languages that do not allow users to define and name types, such as Fortran and COBOL, name equivalence obviously cannot be used.

Object-oriented languages such as Java and C++ bring another kind of type compatibility issue with them. The issue is object compatibility and its relationship to the inheritance hierarchy, which is discussed in Chapter 12.

Type compatibility in expressions is discussed in Chapter 7; type compatibility for subprogram parameters is discussed in Chapter 9.

6.16 Theory and Data Types

Type theory is a broad area of study in mathematics, logic, computer science, and philosophy. It began in mathematics in the early 1900s and later became a standard tool in logic. Any general discussion of type theory is necessarily complex, lengthy, and highly abstract. Even when restricted to computer science, type theory includes such diverse and complex subjects as typed lambda calculus, combinators, the metatheory of bounded quantification, existential types, and higher-order polymorphism. All these topics are far beyond the scope of this book.

In computer science there are two branches of type theory: practical and abstract. The practical branch is concerned with data types in commercial programming languages; the abstract branch primarily focuses on typed lambda calculus, an area of extensive research by theoretical computer scientists over the past half century. This section is restricted to a brief description of some of the mathematical formalisms that underlie data types in programming languages.

A data type defines a set of values and a collection of operations on those values. A **type system** is a set of types and the rules that govern their use in programs. Obviously, every typed programming language defines a type system. The formal model of a type system of a programming language consists of a set of types and a collection of functions that define the type rules of the language, which are used to determine the type of any expression. A formal system that describes the rules of a type system, attribute grammars, is introduced in Chapter 3.

An alternative model to attribute grammars uses a type map and a collection of functions, not associated with grammar rules, that specify the type rules. A type map is similar to the state of a program used in denotational semantics, consisting of a set of ordered pairs, with the first element of each pair being a variable’s name and the second element being its type. A type map is constructed using the type declarations in the program. In a static typed language, the type map need only be maintained during compilation,

although it changes as the program is analyzed by the compiler. If any type checking is done dynamically, the type map must be maintained during execution. The concrete version of a type map in a compilation system is the symbol table, constructed primarily by the lexical and syntax analyzers. Dynamic types sometimes are maintained with tags attached to values or objects.

As stated previously, a data type is a set of values, although in a data type the elements are often ordered. For example, the elements in all enumeration types are ordered. However, in a mathematical set the elements are not ordered. Despite this difference, set operations can be used on data types to describe new data types. The structured data types of programming languages are defined by type operators, or constructors that correspond to set operations. These set operations/type constructors are briefly introduced in the following paragraphs.

A finite mapping is a function from a finite set of values, the domain set, onto values in the range set. Finite mappings model two different categories of types in programming languages, functions and arrays, although in some languages functions are not types. All languages include arrays, which are defined in terms of a mapping function that maps indices to elements in the array. For traditional arrays, the mapping is simple—integer values are mapped to the addresses of array elements; for associative arrays, the mapping is defined by a function that describes a hashing operation. The hashing function maps the keys of the associate arrays, usually character strings,10 to the addresses of the array elements.

10. In Ruby, the associative array keys need not be character strings—they can be any type.

A Cartesian, or cross product of n sets, S1, S2, …, Sn, is a set denoted $S1 \times S2 \times \ldots \times Sn$. Each element of the Cartesian product set has one element from each of the constituent sets. So, $S1 \times S2 = \{(x, y) \mid x \text{ is in } S1 \text{ and } y \text{ is in } S2\}$. For example, if $S1 = \{1, 2\}$ and $S2 = \{a, b\}$, $S1 \times S2 = \{(1, a), (1, b), (2, a), (2, b)\}$. A Cartesian product defines tuples in mathematics, which appear in Python, ML, Swift, and F# as a data type (see Section 6.5). Cartesian products also model records, or structs, although not exactly. Cartesian products do not have element names, but records require

them. For example, consider the following C struct:

```
struct intFloat {
  int myInt;
  float myFloat;
};
```

This struct defines the Cartesian product type **`int`** × **`float`**. The names of the elements are `myInt` and `myFloat`.

The union of two sets, S1 and S2, is defined as S1 ∪ S2={x | x is in S1 or x is in S2}. Set union models the union data types, as described in Section 6.10.

Mathematical subsets are defined by providing a rule that elements must follow. These sets model the subtypes of Ada, although not exactly, because subtypes must consist of contiguous elements of their parent sets. Elements of mathematical sets are unordered, so the model is not perfect.

Notice that pointers, defined with type operators, such as the asterisk in C, are not defined in terms of a set operation.

This concludes our discussion of formalisms in data types, as well as our whole discussion of data types.

SUMMARY

The data types of a language are a large part of what determines that language's style and usefulness. Along with control structures, they form the heart of a language.

The primitive data types of most imperative languages include numeric, character, and Boolean types. The numeric types are often directly supported by hardware.

The user-defined enumeration and subrange types are convenient and add to the readability and reliability of programs.

Arrays are part of most programming languages. The relationship between a reference to an array element and the address of that element is given in an access function, which is an implementation of a mapping. Arrays can be either static, as in C++ arrays whose definition includes the **`static`** specifier; fixed stack-dynamic, as in C functions (without the **`static`** specifier); fixed heap-dynamic, as with Java's objects; or heap dynamic, as in Perl's arrays. Most languages allow only a few operations on complete arrays.

Records are now included in most languages. Fields of records are specified in a variety of ways. In the case of COBOL, they can be referenced without naming all of the enclosing records, although this is messy to implement and harmful to readability. In several languages that support object-oriented programming, records are supported with objects.

Tuples are similar to records, but do not have names for their constituent. parts. They are part of Python, ML, and F#.

Lists are staples of the functional programming languages, but are now also included in Python and C#.

Unions are locations that can store different type values at different times. Discriminated unions include a tag to record the current type value. A free union is one without the tag. Most languages with unions do not have safe

designs for them, the exceptions being ML, Swift, and F#.

Pointers are used for addressing flexibility and to control dynamic storage management. Pointers have some inherent dangers: Dangling pointers are difficult to avoid, and memory leakage can occur.

Reference types, such as those in Java and C#, provide heap management without the dangers of pointers.

Enumeration and record types are relatively easy to implement. Arrays are also straightforward, although array element access is an expensive process when the array has several subscripts. The access function requires one addition and one multiplication for each subscript.

Pointers are relatively easy to implement, if heap management is not considered. Heap management is easy if all cells have the same size but is complicated for variable-size cell allocation and deallocation.

Optional type variables are variables that allow a nonvalue to be stored. This allows a program to indicate when a variable currently has no value.

Strong typing is the concept of requiring that all type errors be detected. The value of strong typing is increased reliability.

The type equivalence rules of a language determine what operations are legal among the structured types of a language. Name type equivalence and structure type equivalence are the two fundamental approaches to defining type equivalence.

Type theories have been developed in many areas. In computer science, the practical branch of type theory defines the types and type rules of programming languages. Set theory can be used to model most of the structured data types in programming languages.

BIBLIOGRAPHIC NOTES

A wealth of literature exists that is concerned with data type design, use, and implementation. Hoare gives one of the earliest systematic definitions of structured types in Dahl et al. (1972). A general discussion of a wide variety of data types is given in Cleaveland (1986).

Implementing run-time checks on the possible insecurities of Pascal data types is discussed in Fischer and LeBlanc (1980). Most compiler design books, such as Fischer and LeBlanc (1991) and Aho et al. (1986), describe implementation methods for data types, as do the other programming language texts, such as Pratt and Zelkowitz (2001) and Scott (2009). A detailed discussion of the problems of heap management can be found in Tenenbaum et al. (1990). Garbage-collection methods are developed by Schorr and Waite (1967) and Deutsch and Bobrow (1976). A comprehensive discussion of garbage-collection algorithms can be found in Cohen (1981) and Wilson (2005).

REVIEW QUESTIONS

1. What is a descriptor?
2. What are the advantages and disadvantages of decimal data types?
3. What are the design issues for character string types?
4. Describe the three string length options.
5. Define *ordinal*, *enumeration*, and *subrange types*.
6. What are the advantages of user-defined enumeration types?
7. In what ways are the user-defined enumeration types of C# more reliable than those of C++?
8. What are the design issues for arrays?
9. Define *static*, *fixed stack-dynamic*, *fixed heap-dynamic*, and *heap-dynamic arrays*. What are the advantages of each?
10. What happens when a nonexistent element of an array is referenced in Perl?
11. How does JavaScript support sparse arrays?
12. What languages support negative subscripts?
13. What languages support array slices with stepsizes?
14. What is an aggregate constant?
15. Define *row major order* and *column major order*.
16. What is an access function for an array?

17. What are the required entries in a Java array descriptor, and when must they be stored (at compile time or run time)?

18. What is the structure of an associative array?

19. What is the purpose of level numbers in COBOL records?

20. Define *fully qualified* and *elliptical references* to fields in records.

21. What is the primary difference between a record and a tuple?

22. Are the tuples of Python mutable?

23. What is the purpose of an F# tuple pattern?

24. In what primarily imperative language do lists serve as arrays?

25. What is the action of the Scheme function `CAR`?

26. What is the action of the F# function `tl`?

27. In what way does Scheme's `CDR` function modify its parameter?

28. On what are Python's list comprehensions based?

29. Define *union*, *free union*, and *discriminated union*.

30. Are the unions of F# discriminated?

31. What are the design issues for pointer types?

32. What are the two common problems with pointers?

33. Why are the pointers of most languages restricted to pointing at a single type variable?

34. What is a C++ reference type, and what is its common use?

35. Why are reference variables in C++ better than pointers for formal

parameters?

36. What advantages do Java and C# reference type variables have over the pointers in other languages?

37. Describe the lazy and eager approaches to reclaiming garbage.

38. Why wouldn't arithmetic on Java and C# references make sense?

39. What is a compatible type?

40. Define type error.

41. Define strongly typed.

42. Why is Java not strongly typed?

43. What is a nonconverting cast?

44. What languages have no type coercions?

45. Why are C and C++ not strongly typed?

46. What is name type equivalence?

47. What is structure type equivalence?

48. What is the primary advantage of name type equivalence?

49. What is the primary disadvantage to structure type equivalence?

50. For what types does C use structure type equivalence?

51. What set operation models C's `struct` data type?

PROBLEM SET

1. What are the arguments for and against representing Boolean values as single bits in memory?

2. How does a decimal value waste memory space?

3. VAX minicomputers use a format for floating-point numbers that is not the same as the IEEE standard. What is this format, and why was it chosen by the designers of the VAX computers? A reference for VAX floating-point representations is Sebesta (1991).

4. Compare the tombstone and lock-and-key methods of avoiding dangling pointers, from the points of view of safety and implementation cost.

5. What disadvantages are there in implicit dereferencing of pointers, but only in certain contexts?

6. Explain all of the differences between Ada's subtypes and derived types.

7. What significant justification is there for the `->` operator in C and C++?

8. What are all of the differences between the enumeration types of C++ and those of Java?

9. Multidimensional arrays can be stored in row major order, as in C++, or in column major order, as in Fortran. Develop the access functions for both of these arrangements for three-dimensional arrays.

10. In the Burroughs Extended ALGOL language, matrices are stored as a single-dimensioned array of pointers to the rows of the matrix, which are treated as single-dimensioned arrays of values. What are the advantages and disadvantages of such a scheme?

11. Analyze and write a comparison of C's `malloc` and `free` functions with C++'s **`new`** and **`delete`** operators. Use safety as the primary

consideration in the comparison.

12. Analyze and write a comparison of using C++ pointers and Java reference variables to refer to fixed heap-dynamic variables. Use safety and convenience as the primary considerations in the comparison.

13. Write a short discussion of what was lost and what was gained in Java's designers' decision to not include the pointers of C++.

14. What are the arguments for and against Java's implicit heap storage recovery, when compared with the explicit heap storage recovery required in C++? Consider real-time systems.

15. What are the arguments for the inclusion of enumeration types in C#, although they were not in the first few versions of Java?

16. What would you expect to be the level of use of pointers in C#? How often will they be used when it is not absolutely necessary?

17. Make two lists of applications of matrices, one for those that require jagged matrices and one for those that require rectangular matrices. Now, argue whether just jagged, just rectangular, or both should be included in a programming language.

18. Compare the string manipulation capabilities of the class libraries of C++, Java, and C#.

19. Look up the definition of *strongly typed* as given in Gehani (1983) and compare it with the definition given in this chapter. How do they differ?

20. In what way is static type checking better than dynamic type checking?

21. Explain how coercion rules can weaken the beneficial effect of strong typing.

PROGRAMMING EXERCISES

1. Design a set of simple test programs to determine the type compatibility rules of a C compiler to which you have access. Write a report of your findings.

2. Determine whether some C compiler to which you have access implements the `free` function.

3. Write a program that does matrix multiplication in some language that does subscript range checking and for which you can obtain an assembly language or machine language version from the compiler. Determine the number of instructions required for the subscript range checking and compare it with the total number of instructions for the matrix multiplication process.

4. If you have access to a compiler in which the user can specify whether subscript range checking is desired, write a program that does a large number of matrix accesses and time their execution. Run the program with subscript range checking and without it, and compare the times.

5. Write a simple program in C++ to investigate the safety of its enumeration types. Include at least 10 different operations on enumeration types to determine what incorrect or just silly things are legal. Now, write a C# program that does the same things and run it to determine how many of the incorrect or silly things are legal. Compare your results.

6. Write a program in C++ or C# that includes two different enumeration types and has a significant number of operations using the enumeration types. Also write the same program using only integer variables. Compare the readability and predict the reliability differences between the two programs.

7. Write a C program that does a large number of references to elements of

two-dimensioned arrays, using only subscripting. Write a second program that does the same operations but uses pointers and pointer arithmetic for the storage-mapping function to do the array references. Compare the time efficiency of the two programs. Which of the two programs is likely to be more reliable? Why?

8. Write a Perl program that uses a hash and a large number of operations on the hash. For example, the hash could store people's names and their ages. A random-number generator could be used to create three-character names and ages, which could be added to the hash. When a duplicate name was generated, it would cause an access to the hash but not add a new element. Rewrite the same program without using hashes. Compare the execution efficiency of the two. Compare the ease of programming and readability of the two.

9. Write a program in the language of your choice that behaves differently if the language used name equivalence than if it used structural equivalence.

10. For what types of A and B is the simple assignment statement A=B legal in C++ but not Java?

7 Expressions and Assignment Statements

As the title indicates, the topic of this chapter is expressions and assignment statements. The semantics rules that determine the order of evaluation of operators in expressions are discussed first. This is followed by an explanation of a potential problem with operand evaluation order when functions can have side effects. Overloaded operators, both predefined and user defined, are then discussed, along with their effects on the expressions in programs. Next, mixed-mode expressions are described and evaluated. This leads to the definition and evaluation of widening and narrowing type conversions, both implicit and explicit. Relational and Boolean expressions are then discussed, including the process of short-circuit evaluation. Finally, the assignment statement, from its simplest form to all of its variations, is - covered, including assignments as expressions and mixed-mode assignments.

Character string pattern-matching expressions were covered as a part of the - material on character strings in Chapter 6, so they are not mentioned in this chapter.

7.1 Introduction

Expressions are the fundamental means of specifying computations in a programming language. It is crucial for a programmer to understand both the syntax and semantics of expressions of the language he or she uses. A formal mechanism (BNF) for describing the syntax of expressions was introduced in Chapter 3. In this chapter, the semantics of expressions are discussed.

To understand expression evaluation, it is necessary to be familiar with the orders of operator and operand evaluation. The operator evaluation order of expressions is dictated by the associativity and precedence rules of the language. Although the value of an expression sometimes depends on it, the order of operand evaluation in expressions is often unstated by language designers. This allows implementors to choose the order, which leads to the possibility of programs producing different results in different implementations. Other issues in expression semantics are type mismatches, coercions, and short-circuit evaluation.

The essence of the imperative programming languages is the dominant role of assignment statements. The purpose of these statements is to cause the side effect of changing the values of variables, or the state, of the program. So an integral part of all imperative languages is the concept of variables whose values change during program execution.

Functional languages use variables of a different sort, such as the parameters of functions. These languages also have declaration statements that bind values to names. These declarations are similar to assignment statements, but do not have side effects.

7.2 Arithmetic Expressions

Automatic evaluation of arithmetic expressions similar to those found in mathematics, science, and engineering was one of the primary goals of the first high-level programming languages. Most of the characteristics of arithmetic expressions in programming languages were inherited from conventions that had evolved in mathematics. In programming languages, arithmetic expressions consist of operators, operands, parentheses, and function calls. An operator can be **unary**, meaning it has a single operand, **binary**, meaning it has two operands, or **ternary**, meaning it has three operands.

In most programming languages, binary operators are **infix**, which means they appear between their operands. One exception is Perl, which has some operators that are **prefix**, which means they precede their operands. In Scheme and Lisp, all operators are prefix. Most unary operators are prefix, but the ++ and -- operators of C-based languages can be either prefix or postfix.

The purpose of an arithmetic expression is to specify an arithmetic computation. An implementation of such a computation must cause two actions: fetching the operands, usually from memory, and executing arithmetic operations on those operands. In the following sections, we investigate the common design details of arithmetic expressions.

Following are the primary design issues for arithmetic expressions, all of which are discussed in this section:

- What are the operator precedence rules?
- What are the operator associativity rules?
- What is the order of operand evaluation?
- Are there restrictions on operand evaluation side effects?

- Does the language allow user-defined operator overloading?
- What type mixing is allowed in expressions?

7.2.1 Operator Evaluation Order

The operator precedence and associativity rules of a language dictate the order of evaluation of its operators.

7.2.1.1 Precedence

The value of an expression depends at least in part on the order of evaluation of the operators in the expression. Consider the following expression:

```
a + b * c
```

Suppose the variables `a`, `b`, and `c` have the values `3`, `4`, and `5`, respectively. If evaluated left to right (the addition first and then the multiplication), the result is `35`. If evaluated right to left, the result is `23`.

Instead of simply evaluating the operators in an expression from left to right or right to left, mathematicians long ago developed the concept of placing operators in a hierarchy of evaluation priorities and basing the evaluation order of expressions partly on this hierarchy. For example, in mathematics, multiplication is considered to be of higher priority than addition, perhaps due to its higher level of complexity. If that convention were applied in the previous example expression, as would be the case in most programming languages, the multiplication would be done first.

The **operator precedence rules** for expression evaluation partially define the order in which the operators of different precedence levels are evaluated. The operator precedence rules for expressions are based on the hierarchy of operator priorities, as seen by the language designer. The operator precedence rules of the common imperative languages are nearly all the same, because they are based on those of mathematics. In these languages, exponentiation

has the highest precedence (when it is provided by the language), followed by multiplication and division on the same level, followed by binary addition and subtraction on the same level.

Many languages also include unary versions of addition and subtraction. Unary addition is called the **identity operator** because it usually has no associated operation and thus has no effect on its operand. Ellis and Stroustrup (1990, p. 56), speaking about C++, call it a historical accident and correctly label it useless. Unary minus, of course, changes the sign of its operand. In Java and C#, unary minus also causes the implicit conversion of `short` and `byte` operands to `int` type.

In all of the common imperative languages, the unary minus operator can appear in an expression either at the beginning or anywhere inside the expression, as long as it is parenthesized to prevent it from being next to another operator. For example,

```
a + (- b) * c
```

is legal, but

```
a + - b * c
```

usually is not.

Next, consider the following expressions:

```
- a / b
- a * b
- a ** b
```

In the first two cases, the relative precedence of the unary minus operator and the binary operator is irrelevant—the order of evaluation of the two operators has no effect on the value of the expression. In the last case, however, it does matter.

Of the common programming languages, only Fortran, Ruby, Visual Basic, and Ada have the exponentiation operator. In all four, exponentiation has higher precedence than unary minus, so

```
- A ** B
```

is equivalent to

```
-(A ** B)
```

The precedences of the arithmetic operators of Ruby and the C-based languages are as follows:

	Ruby	*C-Based Languages*
Highest	**	postfix ++, --
	unary +, -	prefix ++, --, unary +, -
	*, /, %	*, /, %
Lowest	binary +, -	binary +, -

The ** operator is exponentiation. The % operator takes two integer operands and yields the remainder of the first after division by the second.[1] The ++ and -- operators of the C-based languages are described in Section 7.7.4.

1. In versions of C before C99, the % operator was implementation dependent in some situations, because division was also implementation dependent.

APL is odd among languages because it has a single level of precedence, as illustrated in the next section.

Precedence accounts for only some of the rules for the order of operator evaluation; associativity rules also affect it.

7.2.1.2 Associativity

Consider the following expression:

```
a - b + c - d
```

If the addition and subtraction operators have the same level of precedence,

as they do in programming languages, the precedence rules say nothing about the order of evaluation of the operators in this expression.

When an expression contains two adjacent[2] occurrences of operators with the same level of precedence, the question of which operator is evaluated first is answered by the **associativity** rules of the language. An operator can have either left or right associativity, meaning that when there are two adjacent operators with the same precedence, the left operator is evaluated first or the right operator is evaluated first, respectively.

2. We call operators "adjacent" if they are separated by a single operand.

Associativity in common languages is left to right, except that the exponentiation operator (when provided) sometimes associates right to left. In the Java expression

```
a - b + c
```

the left operator is evaluated first.

Exponentiation in Fortran and Ruby is right associative, so in the expression

```
A ** B ** C
```

the right operator is evaluated first.

In Visual Basic, the exponentiation operator, ^, is left associative.

The associativity rules for a few common languages are given here:

Language	*Associativity Rule*
Ruby	Left: *, /, +, -
	Right: **
C-based languages	Left: *, /, %, binary +, binary -
	Right: ++, --, unary -, unary +

As stated in Section 7.2.1.1, in APL, all operators have the same level of precedence. Thus, the order of evaluation of operators in APL expressions is determined entirely by the associativity rule, which is right to left for all operators. For example, in the expression

```
A × B + C
```

the addition operator is evaluated first, followed by the multiplication operator (× is the APL multiplication operator). If `A` were `3`, `B` were `4`, and `C` were `5`, then the value of this APL expression would be `27`.

Many compilers for the common languages make use of the fact that some arithmetic operators are mathematically associative, meaning that the associativity rules have no impact on the value of an expression containing only those operators. For example, addition is mathematically associative, so in mathematics the value of the expression

```
A + B + C
```

does not depend on the order of operator evaluation. If floating-point operations for mathematically associative operations were also associative, the compiler could use this fact to perform some simple optimizations. Specifically, if the compiler is allowed to reorder the evaluation of operators, it may be able to produce slightly faster code for expression evaluation. Compilers commonly do these kinds of optimizations.

Unfortunately, in a computer, both floating-point representations and floating-point arithmetic operations are only approximations of their mathematical counterparts (because of size limitations). The fact that a mathematical operator is associative does not necessarily imply that the corresponding computer floating-point operation is associative. In fact, only if all the operands and intermediate results can be exactly represented in floating-point notation will the process be precisely associative. For example, there are pathological situations in which integer addition on a computer is *not* associative. For example, suppose that a program must evaluate the expression

```
A + B + C + D
```

and that `A` and `C` are very large positive numbers, and `B` and `D` are negative numbers with very large absolute values. In this situation, adding `B` to `A` does not cause an overflow exception, but adding `C` to `A` does. Likewise, adding `C` to `B` does not cause overflow, but adding `D` to `B` does. Because of the limitations of computer arithmetic, addition is catastrophically nonassociative in this case. Therefore, if the compiler reorders these addition operations, it affects the value of the expression. This problem, of course, can be avoided by the programmer, assuming the approximate values of the variables are known. The programmer can specify the expression in two parts (in two assignment statements), ensuring that overflow is avoided. However, this situation can arise in far more subtle ways, in which the programmer is less likely to notice the order dependence.

7.2.1.3 Parentheses

Programmers can alter the precedence and associativity rules by placing parentheses in expressions. A parenthesized part of an expression has precedence over its adjacent unparenthesized parts. For example, although multiplication has precedence over addition, in the expression

```
(A + B) * C
```

the addition will be evaluated first. Mathematically, this is perfectly natural. In this expression, the first operand of the multiplication operator is not available until the addition in the parenthesized subexpression is evaluated. Also, the expression from Section 7.2.1.2 could be specified as

```
(A + B) + (C + D)
```

to avoid overflow.

Languages that allow parentheses in arithmetic expressions could dispense with all precedence rules and simply associate all operators left to right or right to left. The programmer would specify the desired order of evaluation with parentheses. This approach would be simple because neither the author nor the readers of programs would need to remember any precedence or associativity rules. The disadvantage of this scheme is that it makes writing

expressions more tedious, and it also seriously compromises the readability of the code. Yet this was the choice made by Ken Iverson, the designer of APL.

7.2.1.4 Ruby Expressions

Recall that Ruby is a pure object-oriented language, which means, among other things, that every data value, including literals, is an object. Ruby supports the collection of arithmetic and logic operations that are included in the C-based languages. What sets Ruby apart from the C-based languages in the area of expressions is that all of the arithmetic, relational, and assignment operators, as well as array indexing, shifts, and bitwise logic operators, are implemented as methods. For example, the expression `a + b` is a call to the `+` method of the object referenced by `a`, passing the object referenced by `b` as a parameter.

One interesting result of the implementation of operators as methods is that they can be overridden by application programs. Therefore, these operators can be redefined. While it is often not useful to redefine operators for predefined types, it is useful, as we will see in Section 7.3, to define predefined operators for user-defined types, which can be done with operator overloading in some languages.

In C++ and Ada, operators are actually implemented as function calls.

7.2.1.5 Expressions in Lisp

As is the case with Ruby, all arithmetic and logic operations in Lisp are performed by subprograms. But in Lisp, the subprograms must be explicitly called. For example, to specify the C expression `a + b * c` in Lisp, one must write the following expression:[3]

3. When a list is interpreted as code in Lisp, the first element is the function name and others are parameters to the function.

```
(+ a (* b c))
```

In this expression, `+` and `*` are the names of functions.

7.2.1.6 Conditional Expressions

`if-then-else` statements can be used to perform a conditional expression assignment. For example, consider

```
if  (count == 0)
  average = 0;
else
  average = sum / count;
```

In the C-based languages, this code can be specified more conveniently in an assignment statement using a conditional expression, which has the following form:

- expression_1 ? expression_2 : expression_3

where expression_1 is interpreted as a Boolean expression. If expression_1 evaluates to true, the value of the whole expression is the value of expression_2; otherwise, it is the value of expression_3. For example, the effect of the example **`if-then-else`** can be achieved with the following assignment statement, using a conditional expression:

```
average = (count == 0) ? 0 : sum / count;
```

In effect, the question mark denotes the beginning of the **`then`** clause, and the colon marks the beginning of the **`else`** clause. Both clauses are mandatory. Note that **`?`** is used in conditional expressions as a ternary operator.

Conditional expressions can be used anywhere in a program (in a C-based language) where any other expression can be used. In addition to the C-based languages, conditional expressions are provided in Perl, JavaScript, and Ruby.

7.2.2 Operand Evaluation Order

A less commonly discussed design characteristic of expressions is the order of evaluation of operands. Variables in expressions are evaluated by fetching their values from memory. Constants are sometimes evaluated the same way. In other cases, a constant may be part of the machine language instruction and not require a memory fetch. If an operand is a parenthesized expression, all of the operators it contains must be evaluated before its value can be used as an operand.

If neither of the operands of an operator has side effects, then operand evaluation order is irrelevant. Therefore, the only interesting case arises when the evaluation of an operand does have side effects.

7.2.2.1 Side Effects

A **side effect** of a function, naturally called a functional side effect, occurs when the function changes either one of its parameters or a global variable. (A global variable is declared outside the function but is accessible in the function.)

Consider the following expression:

```
a + fun(a)
```

If `fun` does not have the side effect of changing `a`, then the order of evaluation of the two operands, `a` and `fun(a)`, has no effect on the value of the expression. However, if `fun` changes `a`, there is an effect. Consider the following situation: `fun` returns `10` and changes the value of its parameter to `20`. Suppose we have the following:

```
a = 10;
b = a + fun(a);
```

Then, if the value of `a` is fetched first (in the expression evaluation process), its value is `10` and the value of the expression is `20`. But if the second operand

is evaluated first, then the value of the first operand is `20` and the value of the expression is `30`.

The following C program illustrates the same problem when a function changes a global variable that appears in an expression:

```
int a = 5;
int fun1() {
   a = 17;
   return  3;
}   /* end of fun1 */
 void  main() {
   a = a + fun1();
}   /* end of main */
```

The value computed for `a` in `main` depends on the order of evaluation of the operands in the expression `a + fun1()`. The value of `a` will be either `8` (if `a` is evaluated first) or `20` (if the function call is evaluated first).

Note that functions in mathematics do not have side effects, because there is no notion of variables in mathematics. The same is true for functional programming languages. In both mathematics and functional programming languages, functions are much easier to reason about and understand than those in imperative languages, because their context is irrelevant to their meaning.

There are two possible solutions to the problem of operand evaluation order and side effects. First, the language designer could disallow function evaluation from affecting the value of expressions by simply disallowing functional side effects. Second, the language definition could state that operands in expressions are to be evaluated in a particular order and demand that implementors guarantee that order.

Disallowing functional side effects in the imperative languages is difficult, and it eliminates some flexibility for the programmer. Consider the case of C and C++, which have only functions, meaning that all subprograms return one value. To eliminate the side effects of two-way parameters and still provide subprograms that return more than one value, the values would need to be placed in a struct and the struct returned. Access to globals in functions would also have to be disallowed. However, when efficiency is important,

using access to global variables to avoid parameter passing is an important method of increasing execution speed. In compilers, for example, global access to data such as the symbol table is commonplace.

The problem with having a strict evaluation order is that some code optimization techniques used by compilers involve reordering operand evaluations. A guaranteed order disallows those optimization methods when function calls are involved. There is, therefore, no perfect solution, as is borne out by actual language designs.

The Java language definition guarantees that operands appear to be evaluated in left-to-right order, eliminating the problem discussed in this section.

7.2.2.2 Referential Transparency and Side Effects

The concept of referential transparency is related to and affected by functional side effects. A program has the property of **referential transparency** if any two expressions in the program that have the same value can be substituted for one another anywhere in the program, without affecting the action of the program. The value of a referentially transparent function depends entirely on its parameters.4 The connection of referential transparency and functional side effects is illustrated by the following example:

4. Furthermore, the value of the function cannot depend on the order in which its parameters are evaluated.

```
result1 = (fun(a) + b) / (fun(a) - c);
temp = fun(a);
result2 = (temp + b) / (temp - c);
```

If the function `fun` has no side effects, `result1` and `result2` will be equal, because the expressions assigned to them are equivalent. However, suppose `fun` has the side effect of adding 1 to either `b` or `c`. Then `result1` would not be equal to `result2`. So, that side effect violates the referential transparency

of the program in which the code appears.

There are several advantages to referentially transparent programs. The most important of these is that the semantics of such programs is much easier to understand than the semantics of programs that are not referentially transparent. Being referentially transparent makes a function equivalent to a mathematical function, in terms of ease of understanding.

Because they do not have variables, programs written in pure functional languages are referentially transparent. Functions in a pure functional language cannot have state, which would be stored in local variables. If such a function uses a value from outside the function, that value must be a constant, since there are no variables. Therefore, the value of the function depends on the values of its parameters.

Referential transparency will be further discussed in Chapter 15.

7.3 Overloaded Operators

Arithmetic operators are often used for more than one purpose. For example, + usually is used to specify integer addition and floating-point addition. Some languages—Java, for example—also use it for string catenation. This multiple use of an operator is called **operator overloading** and is generally thought to be acceptable, as long as neither readability nor reliability suffers.

As an example of the possible dangers of overloading, consider the use of the ampersand (&) in C++. As a binary operator, it specifies a bitwise logical AND operation. As a unary operator, however, its meaning is totally different. As a unary operator with a variable as its operand, the expression value is the address of that variable. In this case, the ampersand is called the address-of operator. For example, the execution of

```
x = &y;
```

causes the address of y to be placed in x. There are two problems with this multiple use of the ampersand. First, using the same symbol for two completely unrelated operations is detrimental to readability. Second, the simple keying error of leaving out the first operand for a bitwise AND operation can go undetected by the compiler, because it is interpreted as an address-of operator. Such an error may be difficult to diagnose.

Virtually all programming languages have a less serious but similar problem, which is often due to the overloading of the minus operator. The problem is only that the compiler cannot tell if the operator is meant to be binary or unary.5 So once again, failure to include the first operand when the operator is meant to be binary cannot be detected as an error by the compiler. However, the meanings of the two operations, unary and binary, are at least closely related, so readability is not adversely affected.

5. ML alleviates this problem by using different symbols for unary and binary minus operators, tilde (') for unary and dash for binary.

Some languages that support abstract data types (see Chapter 11), for

example, C++, C#, and F#, allow the programmer to further overload operator symbols. For instance, suppose a user wants to define the * operator between a scalar integer and an integer array to mean that each element of the array is to be multiplied by the scalar. Such an operator could be defined by writing a function subprogram named * that performs this new operation. The compiler will choose the correct meaning when an overloaded operator is specified, based on the types of the operands, as with language-defined overloaded operators. For example, if this new definition for * is defined in a C# program, a C# compiler will use the new definition for * whenever the * operator appears with a simple integer as the left operand and an integer array as the right operand.

When sensibly used, user-defined operator overloading can aid readability. For example, if + and * are overloaded for a matrix abstract data type and A, B, C, and D are variables of that type, then

```
A * B + C * D
```

can be used instead of

```
MatrixAdd(MatrixMult(A, B), MatrixMult(C, D))
```

On the other hand, user-defined overloading can be harmful to readability. For one thing, nothing prevents a user from defining + to mean multiplication. Furthermore, seeing an * operator in a program, the reader must find both the types of the operands and the definition of the operator to determine its meaning. Any or all of these definitions could be in other files.

Another consideration is the process of building a software system from modules created by different groups. If the different groups overloaded the same operators in different ways, these differences would obviously need to be eliminated before putting the system together.

C++ has a few operators that cannot be overloaded. Among these are the class or structure member operator (.) and the scope resolution operator (::). Interestingly, operator overloading was one of the C++ features that was not copied into Java. However, it did reappear in C#.

The implementation of user-defined operator overloading is discussed in

Chapter 9.

7.4 Type Conversions

Type conversions are either narrowing or widening. A **narrowing conversion** converts a value to a type that cannot store even approximations of all of the values of the original type. For example, converting a `double` to a `float` in Java is a narrowing conversion, because the range of `double` is much larger than that of `float`. A **widening conversion** converts a value to a type that can include at least approximations of all of the values of the original type. For example, converting an `int` to a `float` in Java is a widening conversion. Widening conversions are nearly always safe, meaning that the approximate magnitude of the converted value is maintained. Narrowing conversions are not always safe—sometimes the magnitude of the converted value is changed in the process. For example, if the floating-point value 1.3E25 is converted to an integer in a Java program, the result will not be in any way related to the original value.

Although widening conversions are usually safe, they can result in reduced accuracy. In many language implementations, although integer-to-floating-point conversions are widening conversions, some precision may be lost. For example, in many cases, integers are stored in 32 bits, which allows at least 9 decimal digits of precision. But floating-point values are also stored in 32 bits, with only about seven decimal digits of precision (because of the space used for the exponent). So, integer-to-floating-point widening can result in the loss of two digits of precision.

Coercions of nonprimitive types are, of course, more complex. In Chapter 5, the complications of assignment compatibility of array and record types were discussed. There is also the question of what parameter types and return types of a method allow it to override a method in a superclass—only when the types are the same, or also some other situations. That issue, as well as the concept of subclasses as subtypes, are discussed in Chapter 12.

Type conversions can be either explicit or implicit. The following two subsections discuss these kinds of type conversions.

7.4.1 Coercion in Expressions

One of the design decisions concerning arithmetic expressions is whether an operator can have operands of different types. Languages that allow such expressions, which are called **mixed-mode expressions**, must define conventions for implicit operand type conversions because computers do not have binary operations that take operands of different types. Recall that in Chapter 5, coercion was defined as an implicit type conversion that is initiated by the compiler or runtime system. Type conversions explicitly requested by the programmer are referred to as explicit conversions, or casts, not coercions.

Although some operator symbols may be overloaded, we assume that a computer system, either in hardware or in some level of software simulation, has an operation for each operand type and operator defined in the language.6 For overloaded operators in a language that uses static type binding, the compiler chooses the correct type of operation on the basis of the types of the operands. When the two operands of an operator are not of the same type and that is legal in the language, the compiler must choose one of them to be coerced and generate the code for that coercion. In the following discussion, the coercion design choices of several common languages are examined.

6. This assumption is not true for many languages. An example is given later in this section.

Language designers are not in agreement on the issue of coercions in arithmetic expressions. Those against a broad range of coercions are concerned with the reliability problems that can result from such coercions, because they reduce the benefits of type checking. Those who would rather include a wide range of coercions are more concerned with the loss in flexibility that results from restrictions. The issue is whether programmers should need to be concerned with this category of errors or whether the compiler should detect them.

As a simple illustration of the problem, consider the following Java code:

```
int a;
```

```
float b, c, d;
. . .
d = b * a;
```

Assume that the second operand of the multiplication operator was supposed to be `c`, but because of a keying error it was typed as `a`. Because mixed-mode expressions are legal in Java, the compiler would not detect this as an error. It would simply insert code to coerce the value of the **`int`** operand, `a`, to **`float`**. If mixed-mode expressions were not legal in Java, this keying error would have been detected by the compiler as a type error.

Because error detection is reduced when mixed-mode expressions are allowed, F#, Ada, and ML do not allow them. For example, they do not allow mixing of integer and floating-point operands in expressions.

In most of the other common languages, there are no restrictions on mixed-mode arithmetic expressions.

The C-based languages have integer types that are smaller than the **`int`** type. In Java, these are **`byte`** and **`short`**. Operands of all of these types are coerced to **`int`** whenever virtually any operator is applied to them. So, while data can be stored in variables of these types, it cannot be manipulated before conversion to a larger type. For example, consider the following Java code:

history note

As a more extreme example of the dangers and costs of too much coercion, consider PL/I's efforts to achieve flexibility in expressions. In PL/I, a character string variable can be the operand of an arithmetic operator with an integer as the other operand. At run time, the string is scanned for a numeric value. If the value happens to contain a decimal point, the value is assumed to be of floating-point type, the other operand is coerced to floating point, and the resulting operation is floating-point. This coercion policy is very expensive, because both the type check and the conversion must be done at run time. It also eliminates the possibility of detecting programmer errors in expressions, because a binary operator can combine an operand of any type with an operand of virtually any other type.

```
byte  a, b, c;
. . .
a = b + c;
```

The values of `b` and `c` are coerced to **`int`** and an **`int`** addition is performed. Then, the sum is converted to **`byte`** and put in `a`. Given the large size of the memories of contemporary computers, there is little incentive to use **`byte`** and **`short`**, unless a large number of them must be stored.

7.4.2 Explicit Type Conversion

Most languages provide some capability for doing explicit conversions, both widening and narrowing. In some cases, warning messages are produced when an explicit narrowing conversion results in a significant change to the value of the object being converted.

In the C-based languages, explicit type conversions are called **casts**. To specify a cast, the desired type is placed in parentheses just before the expression to be converted, as in

```
(int)angle
```

One of the reasons for the parentheses around the type name in these conversions is that the first of these languages, C, has several two-word type names, such as **`long int`**.

In ML and F#, the casts have the syntax of function calls. For example, in F# we could have the following:

```
float(sum)
```

7.4.3 Errors in Expressions

A number of errors can occur during expression evaluation. If the language requires type checking, either static or dynamic, then operand type errors cannot occur. The errors that can occur because of coercions of operands in

expressions have already been discussed. The other kinds of errors are due to the limitations of computer arithmetic and the inherent limitations of arithmetic. The most common error occurs when the result of an operation cannot be represented in the memory cell where it must be stored. This is called **overflow** or **underflow**, depending on whether the result was too large or too small. One limitation of arithmetic is that division by zero is disallowed. Of course, the fact that it is not mathematically allowed does not prevent a program from attempting to do it.

Floating-point overflow, underflow, and division by zero are examples of run-time errors, which are sometimes called **exceptions**. Language facilities that allow programs to detect and deal with exceptions are discussed in Chapter 14.

7.5 Relational and Boolean Expressions

In addition to arithmetic expressions, programming languages support relational and Boolean expressions.

7.5.1 Relational Expressions

A **relational operator** is an operator that compares the values of its two operands. A relational expression has two operands and one relational operator. The value of a relational expression is Boolean, except when Boolean is not a type included in the language. The relational operators are often overloaded for a variety of types. The operation that determines the truth or falsehood of a relational expression depends on the operand types. It can be simple, as for integer operands, or complex, as for character string operands. Typically, the types of the operands that can be used for relational operators are numeric types, strings, and enumeration types.

history note

The Fortran I designers used English abbreviations for the relational operators because the symbols > and < were not on the card punches at the time of Fortran I's design (mid-1950s).

The syntax of the relational operators for equality and inequality differs among some programming languages. For example, for inequality, the C-based languages use `!=`, Fortran 95+ uses `.NE.` or <>, and ML and F# use <>.

JavaScript and PHP have two additional relational operators, `===` and `!==`. These are similar to their relatives, == and `!=`, but prevent their operands from being coerced. For example, the expression

```
"7" == 7
```

is true in JavaScript, because when a string and a number are the operands of a relational operator, the string is coerced to a number. However,

```
"7" === 7
```

is false, because no coercion is done on the operands of this operator.

Ruby uses == for the equality relational operator that uses coercions, and `eql?` for equality with no coercions. Ruby uses === only in the **`when`** clause of its **`case`** statement, as discussed in Chapter 8.

The relational operators always have lower precedence than the arithmetic operators, so that in expressions such as

```
a + 1 > 2 * b
```

the arithmetic expressions are evaluated first.

7.5.2 Boolean Expressions

Boolean expressions consist of Boolean variables, Boolean constants, relational expressions, and Boolean operators. The operators usually include those for the AND, OR, and NOT operations, and sometimes for exclusive OR and equivalence. Boolean operators usually take only Boolean operands (Boolean variables, Boolean literals, or relational expressions) and produce Boolean values.

In the mathematics of Boolean algebras, the OR and AND operators must have equal precedence. However, the C-based languages assign a higher precedence to AND than OR. Perhaps this resulted from the baseless correlation of multiplication with AND and of addition with OR, which would naturally assign higher precedence to AND.

Because arithmetic expressions can be the operands of relational expressions, and relational expressions can be the operands of Boolean expressions, the

three categories of operators must be placed in different precedence levels, relative to each other.

The precedence of the arithmetic, relational, and Boolean operators in the C-based languages is as follows:

Highest	postfix ++, --
	unary +, unary -, prefix ++, --, !
	*, /, %
	binary +, binary -
	<, >, <=, >=
	=, !=
	&&
Lowest	||

Versions of C prior to C99 are odd among the popular imperative languages in that they have no Boolean type and thus no Boolean values. Instead, numeric values are used to represent Boolean values. In place of Boolean operands, scalar variables (numeric or character) and constants are used, with zero considered false and all nonzero values considered true. The result of evaluating such an expression is an integer, with the value 0 if false and 1 if true. Arithmetic expressions can also be used for Boolean expressions in C99 and C++.

One odd result of C's design of relational expressions is that the following expression is legal:

```
a > b > c
```

The leftmost relational operator is evaluated first because the relational operators of C are left associative, producing either 0 or 1. Then, this result is

compared with the variable `c`. There is never a comparison between `b` and `c` in this expression.

Some languages, including Perl and Ruby, provide two sets of the binary logic operators, `&&` and **`and`** for AND and `||` and **`or`** for OR. One difference between `&&` and **`and`** (and `||` and **`or`**) is that the spelled versions have lower precedence. Also, **`and`** and **`or`** have equal precedence, but `&&` has higher precedence than `||`.

When the nonarithmetic operators of the C-based languages are included, there are more than 40 operators and at least 14 different levels of precedence. This is clear evidence of the richness of the collections of operators and the complexity of expressions possible in these languages.

Readability dictates that a language should include a Boolean type, as was stated in Chapter 6, rather than simply using numeric types in Boolean expressions. Some error detection is lost in the use of numeric types for Boolean operands, because any numeric expression, whether intended or not, is a legal operand to a Boolean operator. In the other imperative languages, any non-Boolean expression used as an operand of a Boolean operator is detected as an error.

7.6 Short-Circuit Evaluation

A **short-circuit evaluation** of an expression is one in which the result is determined without evaluating all of the operands and/or operators. For example, the value of the arithmetic expression

```
(13 * a) * (b / 13 - 1)
```

is independent of the value of `(b / 13 - 1)` if `a` is `0`, because `0 * x = 0` for any `x`. So, when `a` is `0`, there is no need to evaluate `(b / 13 - 1)` or perform the second multiplication. However, in arithmetic expressions, this shortcut is not easily detected during execution, so it is never taken.

The value of the Boolean expression

```
(a >= 0) && (b < 10)
```

is independent of the second relational expression if `a < 0`, because the expression (`FALSE && (b < 10)`) is `FALSE` for all values of `b`. So, when `a` is less than zero, there is no need to evaluate `b`, the constant `10`, the second relational expression, or the `&&` operation. Unlike the case of arithmetic expressions, this shortcut easily can be discovered during execution.

To illustrate a potential problem with non-short-circuit evaluation of Boolean expressions, suppose Java did not use short-circuit evaluation. A table lookup loop could be written using the **`while`** statement. One simple version of Java code for such a lookup, assuming that `list`, which has `listlen` elements, is the array to be searched and `key` is the searched-for value, is

```
index = 0;
while ((index < listlen) && (list[index] != key))
  index = index + 1;
```

If evaluation is not short-circuit, both relational expressions in the Boolean expression of the **`while`** statement are evaluated, regardless of the value of the first. Thus, if `key` is not in `list`, the program will terminate with a subscript out-of-range exception. The same iteration that has `index == listlen` will

reference `list[listlen]`, which causes the indexing error because list is declared to have `listlen-1` as an upper-bound subscript value.

If a language provides short-circuit evaluation of Boolean expressions and it is used, this is not a problem. In the preceding example, a short-circuit evaluation scheme would evaluate the first operand of the AND operator, but it would skip the second operand if the first operand is false.

A language that provides short-circuit evaluations of Boolean expressions and also has side effects in expressions allows subtle errors to occur. Suppose that short-circuit evaluation is used on an expression and part of the expression that contains a side effect is not evaluated; then the side effect will occur only in complete evaluations of the whole expression. If program correctness depends on the side effect, short-circuit evaluation can result in a serious error. For example, consider the Java expression

```
(a > b) || ((b++) / 3)
```

In this expression, `b` is changed (in the second arithmetic expression) only when `a <= b`. If the programmer assumed `b` would be changed every time this expression is evaluated during execution (and the program's correctness depends on it), the program will fail.

In the C-based languages, the usual AND and OR operators, `&&` and `||`, respectively, are short-circuit. However, these languages also have bitwise AND and OR operators, `&` and `|`, respectively, that can be used on Boolean-valued operands and are not short-circuit. Of course, the bitwise operators are only equivalent to the usual Boolean operators if all operands are restricted to being either `0` (for false) or `1` (for true).

All of the logical operators of Ruby, Perl, ML, F#, and Python are short--circuit evaluated.

7.7 Assignment Statements

As we have previously stated, the assignment statement is one of the central constructs in imperative languages. It provides the mechanism by which the user can dynamically change the bindings of values to variables. In the following section, the simplest form of assignment is discussed. Subsequent sections describe a variety of alternatives.

7.7.1 Simple Assignments

Nearly all programming languages currently being used use the equal sign for the assignment operator. All of these must use something different from an equal sign for the equality relational operator to avoid confusion with their assignment operator.

ALGOL 60 pioneered the use of `:=` as the assignment operator, which avoids the confusion of assignment with equality. Ada also uses this assignment operator.

The design choices of how assignments are used in a language have varied widely. In some languages, such as Fortran and Ada, an assignment can appear only as a stand-alone statement, and the destination is restricted to a single variable. There are, however, many alternatives.

7.7.2 Conditional Targets

Perl allows conditional targets on assignment statements. For example, consider

```
($flag ? $count1 : $count2) = 0;
```

which is equivalent to

```
if ($flag) {
  $count1 = 0;
} else  {
  $count2 = 0;
}
```

7.7.3 Compound Assignment Operators

A **compound assignment operator** is a shorthand method of specifying a commonly needed form of assignment. The form of assignment that can be abbreviated with this technique has the destination variable also appearing as the first operand in the expression on the right side, as in

```
a = a + b
```

Compound assignment operators were introduced by ALGOL 68, were later adopted in a slightly different form by C, and are part of the other C-based languages, as well as Perl, JavaScript, Python, and Ruby. The syntax of these assignment operators is the catenation of the desired binary operator to the = operator. For example,

```
sum += value;
```

is equivalent to

```
sum = sum + value;
```

The languages that support compound assignment operators have versions for most of their binary operators.

7.7.4 Unary Assignment Operators

The C-based languages, Perl, and JavaScript include two special unary

arithmetic operators that are actually abbreviated assignments. They combine increment and decrement operations with assignment. The operators ++ for increment and -- for decrement can be used either in expressions or to form stand-alone single-operator assignment statements. They can appear either as prefix operators, meaning that they precede the operands, or as postfix operators, meaning that they follow the operands. In the assignment statement

```
sum = ++ count;
```

the value of `count` is incremented by `1` and then assigned to `sum`. This operation could also be stated as

```
count = count + 1;
sum = count;
```

If the same operator is used as a postfix operator, as in

```
sum = count ++;
```

the assignment of the value of `count` to `sum` occurs first; then `count` is incremented. The effect is the same as that of the two statements

```
sum = count;
count = count + 1;
```

An example of the use of the unary increment operator to form a complete assignment statement is

```
count ++;
```

which simply increments `count`. It does not look like an assignment, but it certainly is one. It is equivalent to the statement

```
count = count + 1;
```

When two unary operators apply to the same operand, the association is right to left. For example, in

```
- count ++
```

`count` is first incremented and then negated. So, it is equivalent to

```
- (count ++)
```

rather than

```
(- count) ++
```

7.7.5 Assignment as an Expression

In the C-based languages, Perl, and JavaScript, the assignment statement produces a result, which is the same as the value assigned to the target. It can therefore be used as an expression and as an operand in other expressions. This design treats the assignment operator much like any other binary operator, except that it has the side effect of changing its left operand. For example, in C, it is common to write statements such as

```
while ((ch = getchar()) != EOF) { ... }
```

In this statement, the next character from the standard input file, usually the keyboard, is gotten with `getchar` and assigned to the variable `ch`. The result, or value assigned, is then compared with the constant `EOF`. If `ch` is not equal to `EOF`, the compound statement `{...}` is executed. Note that the assignment must be parenthesized—in the languages that support assignment as an expression, the precedence of the assignment operator is lower than that of the relational operators. Without the parentheses, the new character would be compared with `EOF` first. Then, the result of that comparison, either `0` or `1`, would be assigned to `ch`.

The disadvantage of allowing assignment statements to be operands in expressions is that it provides yet another kind of expression side effect. This type of side effect can lead to expressions that are difficult to read and understand. An expression with any kind of side effect has this disadvantage. Such an expression cannot be read as an expression, which in mathematics is a denotation of a value, but only as a list of instructions with an odd order of execution. For example, the expression

```
a = b + (c = d / b) - 1
```

denotes the instructions

```
Assign d / b to c
Assign b + c to temp
Assign temp - 1 to a
```

Note that the treatment of the assignment operator as any other binary operator allows the effect of multiple-target assignments, such as

```
sum = count = 0;
```

in which count is first assigned the zero, and then count's value is assigned to sum. This form of multiple-target assignments is also legal in Python.

There is a loss of error detection in the C design of the assignment operation that frequently leads to program errors. In particular, if we type

```
if  (x = y) ...
```

instead of

```
if  (x == y) ...
```

which is an easily made mistake, it is not detectable as an error by the compiler. Rather than testing a relational expression, the value that is assigned to `x` is tested (in this case, it is the value of `y` that reaches this statement). This is actually a result of two design decisions: allowing assignment to behave like an ordinary binary operator and using two very similar operators, = and ==, to have completely different meanings. This is another example of the safety deficiencies of C and C++ programs. Note that Java and C# allow only **`boolean`** expressions in their **`if`** statements, disallowing this problem.

7.7.6 Multiple Assignments

Several recent programming languages, including Perl and Ruby provide

multiple-target, multiple-source assignment statements. For example, in Perl one can write

```
($first, $second, $third) = (20, 40, 60);
```

The semantics is that `20` is assigned to `$first`, `40` is assigned to `$second`, and `60` is assigned to `$third`. If the values of two variables must be interchanged, this can be done with a single assignment, as with

```
($first, $second) = ($second, $first);
```

This correctly interchanges the values of `$first` and `$second`, without the use of a temporary variable (at least one created and managed by the programmer).

history note

The PDP-11 computer, on which C was first implemented, has autoincrement and autodecrement addressing modes, which are hardware versions of the increment and decrement operators of C when they are used as array indices. One might guess from this that the design of these C operators was based on the design of the PDP-11 architecture. That guess would be wrong, however, because the C operators were inherited from the B language, which was designed before the first PDP-11.

The syntax of the simplest form of Ruby’s multiple assignment is similar to that of Perl, except the left and right sides are not parenthesized. Also, Ruby includes a few more elaborate versions of multiple assignments, which are not discussed here.

7.7.7 Assignment in Functional Programming Languages

All of the identifiers used in pure functional languages and some of them

used in other functional languages are just names of values. As such, their values never change. For example, in ML, names are bound to values with the **`val`** declaration, whose form is exemplified in the following:

```
val cost = quantity * price;
```

If `cost` appears on the left side of a subsequent **`val`** declaration, that declaration creates a new version of the name `cost`, which has no relationship with the previous version, which is then hidden.

F# has a somewhat similar declaration that uses the **`let`** reserved word. The difference between F#'s **`let`** and ML's **`val`** is that **`let`** creates a new scope, whereas **`val`** does not. In fact, **`val`** declarations are often nested in **`let`** constructs in ML. **`let`** and **`val`** are further discussed in Chapter 15.

7.8 Mixed-Mode Assignment

Mixed-mode expressions were discussed in Section 7.4.1. Frequently, assignment statements also are mixed mode. The design question is: Does the type of the expression have to be the same as the type of the variable being assigned, or can coercion be used in some cases of type mismatch?

C, C++, and Perl use coercion rules for mixed-mode assignment that are similar to those they use for mixed-mode expressions; that is, many of the possible type mixes are legal, with coercion freely applied.7

7. Note that in Python and Ruby, types are associated with objects, not variables, so there is no such thing as mixed-mode assignment in those languages.

In a clear departure from C++, Java and C# allow mixed-mode assignment only if the required coercion is widening.8 So, an `int` value can be assigned to a `float` variable, but not vice versa. Disallowing half of the possible mixed-mode assignments is a simple but effective way to increase the reliability of Java and C#, relative to C and C++.

8. Not quite true: If an integer literal, which the compiler by default assigns the type `int`, is assigned to a **char**, `byte`, or `short` variable and the literal is in the range of the type of the variable, the `int` value is coerced to the type of the variable in a narrowing conversion. This narrowing conversion cannot result in an error.

Of course, in functional languages, where assignments are just used to name values, there is no such thing as a mixed-mode assignment.

SUMMARY

Expressions consist of constants, variables, parentheses, function calls, and operators. Assignment statements include target variables, assignment operators, and expressions.

The semantics of an expression is determined in large part by the order of evaluation of operators. The associativity and precedence rules for operators in the expressions of a language determine the order of operator evaluation in those expressions. Operand evaluation order is important if functional side effects are possible. Type conversions can be widening or narrowing. Some narrowing conversions produce erroneous values. Implicit type conversions, or coercions, in expressions are common, although they eliminate the error--detection benefit of type checking, thus lowering reliability.

Assignment statements have appeared in a wide variety of forms, including conditional targets, assigning operators, and list assignments.

REVIEW QUESTIONS

1. Define *operator precedence* and *operator associativity*.
2. What is a ternary operator?
3. What is a prefix operator?
4. What operator usually has right associativity?
5. What is a nonassociative operator?
6. What associativity rules are used by APL?
7. What is the difference between the way operators are implemented in C++ and Ruby?
8. Define *functional side effect*.
9. What is a coercion?
10. What is a conditional expression?
11. What is an overloaded operator?
12. Define *narrowing* and *widening conversions*.
13. In JavaScript, what is the difference between == and ===?
14. What is a mixed-mode expression?
15. What is referential transparency?
16. What are the advantages of referential transparency?
17. How does operand evaluation order interact with functional side effects?

18. What is short-circuit evaluation?

19. Name a language that always does short-circuit evaluation of Boolean expressions. Name one that never does it.

20. How does C support relational and Boolean expressions?

21. What is the purpose of a compound assignment operator?

22. What is the associativity of C's unary arithmetic operators?

23. What is one possible disadvantage of treating the assignment operator as if it were an arithmetic operator?

24. What two languages include multiple assignments?

25. What mixed-mode assignments are allowed in Java?

26. What mixed-mode assignments are allowed in ML?

27. What is a cast?

PROBLEM SET

1. When might you want the compiler to ignore type differences in an expression?

2. State your own arguments for and against allowing mixed-mode arithmetic expressions.

3. Do you think the elimination of overloaded operators in your favorite language would be beneficial? Why or why not?

4. Would it be a good idea to eliminate all operator precedence rules and require parentheses to show the desired precedence in expressions? Why or why not?

5. Should C's assigning operations (for example, `+=`) be included in other languages (that do not already have them)? Why or why not?

6. Should C's single-operand assignment forms (for example, `++count`) be included in other languages (that do not already have them)? Why or why not?

7. Describe a situation in which the add operator in a programming language would not be commutative.

8. Describe a situation in which the add operator in a programming language would not be associative.

9. Assume the following rules of associativity and precedence for expressions:

Precedence	*Highest*	*, /, **not**
		+, −, &, **mod**
		- (unary)
		=, / =, <, <=, >=, >
		and
	Lowest	**or**, **xor**
Associativity	*Left to right*	

Show the order of evaluation of the following expressions by parenthesizing all subexpressions and placing a superscript on the right parenthesis to indicate order. For example, for the expression

```
a + b * c + d
```

the order of evaluation would be represented as

```
((a + (b * c)1)2  + d)3
```

1. `a * b - 1 + c`
2. `a * (b - 1) / c` **mod** `d`
3. `(a - b) / c & (d * e / a - 3)`
4. `-a` **or** `c = d` **and** `e`
5. `a > b` **xor** `c` **or** `d <= 17`
6. `-a + b`

10. Show the order of evaluation of the expressions of Problem 9, assuming that there are no precedence rules and all operators associate right to left.

11. Write a BNF description of the precedence and associativity rules defined for the expressions in Problem 9. Assume the only operands are the names `a,b,c,d,` and `e`.

12. Using the grammar of Problem 11, draw parse trees for the expressions of Problem 9.

13. Let the function `fun` be defined as

```
int fun(int* k) {
 *k += 4;
 return 3 * (*k) - 1;
 }
```

Suppose `fun` is used in a program as follows:

```
void  main() {
  int i = 10, j = 10, sum1, sum2;
  sum1 = (i / 2) + fun(&i);
  sum2 = fun(&j) + (j / 2);
}
```

What are the values of `sum1` and `sum2`

1. operands in the expressions are evaluated left to right?

2. operands in the expressions are evaluated right to left?

14. What is your primary argument against (or for) the operator precedence rules of APL?

15. Explain why it is difficult to eliminate functional side effects in C.

16. For some language of your choice, make up a list of operator symbols that could be used to eliminate all operator overloading.

17. Determine whether the narrowing explicit type conversions in two languages you know provide error messages when a converted value loses its usefulness.

18. Should an optimizing compiler for C or C++ be allowed to change the order of subexpressions in a Boolean expression? Why or why not?

19. Consider the following C program:

```
int fun(int *i) {
  *i += 5;
  return  4;
}
void main() {
  int x = 3;
  x = x + fun(&x);
  }
```

What is the value of x after the assignment statement in main, assuming

1. operands are evaluated left to right.

2. operands are evaluated right to left.

20. Why does Java specify that operands in expressions are all evaluated in left-to-right order?

21. Explain how the coercion rules of a language affect its error detection.

PROGRAMMING EXERCISES

1. Run the code given in Problem 13 (in the Problem Set) on some system that supports C to determine the values of `sum1` and `sum2`. Explain the results.

2. Rewrite the program of Programming Exercise 1 in C++, Java, and C#, run them, and compare the results.

3. Write a test program in your favorite language that determines and outputs the precedence and associativity of its arithmetic and Boolean operators.

4. Write a Java program that exposes Java's rule for operand evaluation order when one of the operands is a method call.

5. Repeat Programming Exercise 4 with C++.

6. Repeat Programming Exercise 4 with C#.

7. Write a program in either C++, Java, or C# that illustrates the order of evaluation of expressions used as actual parameters to a method.

8. Write a C program that has the following statements:

```
int  a, b;
a = 10;
b = a + fun();
printf("With the function call on the right, ");
printf(" b is: %d\n", b);
a = 10;
b = fun() + a;
printf("With the function call on the left, ");
printf(" b is: %d\n", b);
```

   and define `fun` to add 10 to `a`. Explain the results.

9. Write a program in either Java, C++, or C# that performs a large number

of floating-point operations and an equal number of integer operations and compare the time required.

8 Statement-Level Control Structures

The flow of control, or execution sequence, in a program can be examined at several levels. In Chapter 7, the flow of control within expressions, which is - governed by operator associativity and precedence rules, was discussed. At the highest level is the flow of control among program units, which is discussed in Chapters 9 and 13. Between these two extremes is the important issue of the flow of control among statements, which is the subject of this chapter.

We begin by giving an overview of the evolution of control statements. This topic is followed by a thorough examination of selection statements, both those for two-way and those for multiple selection. Next, we discuss the variety of looping statements that have been developed and used in programming languages. Next, we take a brief look at the problems associated with unconditional branch statements. Finally, we describe the guarded command control statements.

8.1 Introduction

Computations in imperative-language programs are accomplished by evaluating expressions and assigning the resulting values to variables. However, there are few useful programs that consist entirely of assignment statements. At least two additional linguistic mechanisms are necessary to make the computations in programs flexible and powerful: some means of selecting among alternative control flow paths (of statement execution) and some means of causing the repeated execution of statements or sequences of statements. Statements that provide these kinds of capabilities are called **control statements**.

Computations in functional programming languages are accomplished by evaluating expressions and applying functions to given parameters. Furthermore, the flow of execution among the expressions and functions is controlled by other expressions and functions, although some of them are similar to the control statements in the imperative languages.

The control statements of the first successful programming language, Fortran, were, in effect, designed by the architects of the IBM 704. All were directly related to machine language instructions, so their capabilities were more the result of instruction design rather than language design. At the time, little was known about the difficulty of programming, and, as a result, the control statements of Fortran in the mid-1950s were thought to be entirely adequate. By today's standards, however, they are considered seriously lacking.

A great deal of research and discussion was devoted to control statements in the 10 years between the mid-1960s and the mid-1970s. One of the primary conclusions of these efforts was that, although a single control statement (a selectable goto) is minimally sufficient, a language that is designed *not* to include a goto needs only a small number of different control statements. In fact, it was proven that all algorithms that can be expressed by flowcharts can be coded in a programming language with only two control statements: one for choosing between two control flow paths and one for logically controlled iterations (Böhm and Jacopini, 1966). An important result of this is that the

unconditional branch statement is superfluous—potentially useful but nonessential. This fact, combined with the practical problems of using unconditional branches, or gotos, led to a great deal of debate about the goto, as will be discussed in Section 8.4.

Programmers care less about the results of theoretical research on control statements than they do about writability and readability. All languages that have been widely used include more control statements than the two that are minimally required, because writability is enhanced by a larger number and wider variety of control statements. For example, rather than requiring the use of a logically controlled loop statement for all loops, it is easier to write programs when a counter-controlled loop statement can be used to build loops that are naturally controlled by a counter. The primary factor that restricts the number of control statements in a language is readability, because the presence of a large number of statement forms demands that program readers learn a larger language. Recall that few people learn all of the statements of a relatively large language; instead, they learn the subset they choose to use, which is often a different subset from that used by the programmer who wrote the program they are trying to read. On the other hand, too few control statements can require the use of lower-level statements, such as the goto, which also makes programs less readable.

The question as to the best collection of control statements to provide the required capabilities and the desired writability has been widely debated. It is essentially a question of how much a language should be expanded to increase its writability at the expense of its simplicity, size, and readability.

A **control structure** is a control statement and the collection of statements whose execution it controls.

There is only one design issue that is relevant to all of the selection and iteration control statements: Should the control structure have multiple entries? All selection and iteration constructs control the execution of code segments, and the question is whether the execution of those code segments always begins with the first statement in the segment. It is now generally believed that multiple entries add little to the flexibility of a control statement, relative to the decrease in readability caused by the increased complexity. Note that multiple entries are possible only in languages that

include gotos and statement labels.

At this point, the reader might wonder why multiple exits from control structures are not considered a design issue. The reason is that all programming languages allow some form of multiple exits from control structures, the rationale being as follows: If all exits from a control structure are restricted to transferring control to the first statement following the structure, where control would flow if the control structure had no explicit exit, there is no harm to readability and also no danger. However, if an exit can have an unrestricted target and therefore can result in a transfer of control to anywhere in the program unit that contains the control structure, the harm to readability is the same as for a goto statement anywhere else in a program. Languages that have a goto statement allow it to appear anywhere, including in a control structure. Therefore, the issue is the inclusion of a goto, not whether multiple exits from control expressions are allowed.

8.2 Selection Statements

A **selection statement** provides the means of choosing between two or more execution paths in a program. Such statements are fundamental and essential parts of all programming languages, as was proven by Böhm and Jacopini.

Selection statements fall into two general categories: two-way and n-way, or multiple selection. Two-way selection statements are discussed in Section 8.2.1; multiple-selection statements are covered in Section 8.2.2.

8.2.1 Two-Way Selection Statements

Although the two-way selection statements of contemporary imperative languages are quite similar, there are some variations in their designs. The general form of a two-way selector is as follows:

`if` control_expression

then clause

else clause

8.2.1.1 Design Issues

The design issues for two-way selectors can be summarized as follows:

- What is the form and type of the expression that controls the selection?
- How are the then and else clauses specified?
- How should the meaning of nested selectors be specified?

8.2.1.2 The Control Expression

Control expressions are specified in parentheses if the **`then`** reserved word (or some other syntactic marker) is not used to introduce the then clause. In those cases where the **`then`** reserved word (or alternative marker) is used, there is less need for the parentheses, so they are often omitted, as in Ruby.

In C89, which did not have a Boolean data type, arithmetic expressions were used as control expressions. This can also be done in Python, C99, and C++. However, in those languages either arithmetic or Boolean expressions can be used. In other contemporary languages, only Boolean expressions can be used for control expressions.

8.2.1.3 Clause Form

In many languages, the then and else clauses appear as either single statements or compound statements. One variation of this is Perl, in which all then and else clauses must be compound statements, even if they have only one statement. Many languages use braces to form compound statements, which serve as the bodies of then and else clauses. In Python and Ruby, the then and else clauses are statement sequences, rather than compound statements. The complete selection statement is terminated in these languages with a reserved word.

Python uses indentation to specify compound statements. For example,

```
if x > y :
  x = y
  print "case 1"
```

All statements equally indented are included in the compound statement.1 Notice that rather than **`then`**, a colon is used to introduce the then clause in Python.

1. The statement following the compound statement must have the same indentation as the `if`.

The variations in clause form have implications for the specification of the meaning of nested selectors, as discussed in the next subsection.

8.2.1.4 Nesting Selectors

Recall that in Chapter 3, we discussed the problem of syntactic ambiguity of a straightforward grammar for a two-way selector statement. That ambiguous grammar was as follows:

<if_stmt> → **if** <logic_expr> **then** <stmt>

| **if** <logic_expr> **then** <stmt> **else** <stmt>

The issue is that when a selection statement is nested in the then clause of a selection statement, it is not clear with which if an else clause should be associated. This problem is reflected in the semantics of selection statements. Consider the following Java-like code:

```
if (sum == 0)
  if (count == 0)
    result = 0;
else
    result = 1;
```

This statement can be interpreted in two different ways, depending on whether the else clause is matched with the first then clause or the second. Notice that the indentation seems to indicate that the else clause belongs with the first then clause. However, with the exceptions of Python and F#, indentation has no effect on semantics in contemporary languages and is therefore ignored by their compilers.

The crux of the problem in this example is that the else clause follows two then clauses with no intervening else clause, and there is no syntactic indicator to specify a matching of the else clause to one of the then clauses. In Java, as in many other imperative languages, the static semantics of the language specify that the else clause is always paired with the nearest previous unpaired then clause. A static semantics rule, rather than a syntactic entity, is used to provide the disambiguation. So, in the example, the else

clause would be paired with the second then clause. The disadvantage of using a rule rather than some syntactic entity is that although the programmer may have meant the else clause to be the alternative to the first then clause and the compiler found the structure syntactically correct, its semantics is the opposite. To force the alternative semantics in Java, the inner **`if`** is put in a compound, as in

```
if (sum == 0) {
  if (count == 0)
    result = 0;
}
else
    result = 1;
```

C, C++, and C# have the same problem as Java with selection statement nesting. Because Perl requires that all then and else clauses be compound, it does not. In Perl, the previous code would be written as follows:

```
if (sum == 0) {
  if (count == 0) {
    result = 0;
  }
} else {
    result = 1;
}
```

If the alternative semantics were needed, it would be

```
if (sum == 0) {
  if (count == 0) {
    result = 0;
  }
  else {
    result = 1;
  }
}
```

Another way to avoid the issue of nested selection statements is to use an alternative means of forming compound statements. Consider the syntactic structure of the Java **`if`** statement. The then clause follows the control expression and the else clause is introduced by the reserved word **`else`**. When the then clause is a single statement and the else clause is present, although

there is no need to mark the end, the **else** reserved word in fact marks the end of the then clause. When the then clause is a compound, it is terminated by a right brace. However, if the last clause in an **if**, whether then or else, is not a compound, there is no syntactic entity to mark the end of the whole selection statement. The use of a special word for this purpose resolves the question of the semantics of nested selectors and also adds to the readability of the statement. This is the design of the selection statement in Ruby. For example, consider the following Ruby statement:

```
if a > b then sum = sum + a
  acount = acount + 1
else sum = sum + b
  bcount = bcount + 1
end
```

The design of this statement is more regular than that of the selection statements of the C-based languages, because the form is the same regardless of the number of statements in the then and else clauses. (This is also true for Perl.) Recall that in Ruby, the then and else clauses consist of statement sequences rather than compound statements. The first interpretation of the selector example at the beginning of this section, in which the else clause is matched to the nested **if**, can be written in Ruby as follows:

```
if sum == 0  then
  if count == 0 then
    result = 0
  else
    result = 1
  end
end
```

Because the **end** reserved word closes the nested **if**, it is clear that the else clause is matched to the inner then clause.

The second interpretation of the selection statement at the beginning of this section, in which the else clause is matched to the outer **if**, can be written in Ruby as follows:

```
if sum == 0 then
  if count == 0 then
    result = 0
```

```
  end
else
    result = 1
 end
```

The following statement, written in Python, is semantically equivalent to the last Ruby statement above:

```
if sum == 0 :
  if count == 0 :
    result = 0
else:
  result = 1
```

If the line **`else:`** were indented to begin in the same column as the nested **`if`**, the else clause would be matched with the inner **`if`**.

ML does not have a problem with nested selectors because it does not allow else-less **`if`** statements.

8.2.1.5 Selector Expressions

In the functional languages ML, F#, and LISP, the selector is not a statement; it is an expression that results in a value. Therefore, it can appear anywhere any other expression can appear. Consider the following example selector written in F#:

```
let y =
    if x > 0 then  x
    else 2 * x;;
```

This creates the name `y` and sets it to either `x` or `2 * x`, depending on whether `x` is greater than zero.

In F#, the type of the value returned by the then clause of an **`if`** construct must be the same as that of the value returned by its else clause. If there is no else clause, the then clause cannot return a value of a normal type. In this case, it can only return a **`unit`** type, which is a special type that means no value. A **`unit`** type is represented in code as `()`.

8.2.2 Multiple-Selection Statements

The **multiple-selection** statement allows the selection of one of any number of statements or statement groups. It is, therefore, a generalization of a selector. In fact, two-way selectors can be built with a multiple selector.

The need to choose from among more than two control paths in programs is common. Although a multiple selector can be built from two-way selectors and gotos, the resulting structures are cumbersome, unreliable, and difficult to write and read. Therefore, the need for a special structure is clear.

8.2.2.1 Design Issues

Some of the design issues for multiple selectors are similar to some of those for two-way selectors. For example, one issue is the question of the type of expression on which the selector is based. In this case, the range of possibilities is larger, in part because the number of possible selections is larger. A two-way selector needs an expression with only two possible values. Another issue is whether single statements, compound statements, or statement sequences may be selected. Next, there is the question of whether only a single selectable segment can be executed when the statement is executed. This is not an issue for two-way selectors, because they always allow only one of the clauses to be on a control path during one execution. As we shall see, the resolution of this issue for multiple selectors is a trade-off between reliability and flexibility. Another issue is the form of the case value specifications. Finally, there is the issue of what should result from the selector expression evaluating to a value that does not select one of the segments. (Such a value would be unrepresented among the selectable segments.) The choice here is between simply disallowing the situation from arising and having the statement do nothing at all when it does arise.

The following is a summary of these design issues:

- What is the form and type of the expression that controls the selection?
- How are the selectable segments specified?
- Is execution flow through the structure restricted to include just a single selectable segment?
- How are the case values specified?
- How should unrepresented selector expression values be handled, if at all?

8.2.2.2 Examples of Multiple Selectors

The C multiple-selector statement, **`switch`**, which is also part of C++, Java, and JavaScript, is a relatively primitive design. Its general form is

```
switch (expression) {
  case constant_ expression1: statement1;
  . . .
  case constantn: statement_n;
  [default: statementn+1]
}
```

where the control expression and the constant expressions are some discrete type. This includes integer types, as well as characters and enumeration types. The selectable statements can be statement sequences, compound statements, or blocks. The optional **`default`** segment is for unrepresented values of the control expression. If the value of the control expression is not represented and no default segment is present, then the statement does

nothing.

The **switch** statement does not provide implicit branches at the end of its code segments. This allows control to flow through more than one selectable code segment on a single execution. Consider the following example:

```
switch  (index) {
   case  1:
   case  3: odd += 1;
          sumodd += index;
   case  2:
   case  4: even += 1;
          sumeven += index;
   default: printf("Error in switch, index = %d\n", index);
}
```

This code prints the error message on every execution. Likewise, the code for the 2 and 4 constants is executed every time the code at the 1 or 3 constants is executed. To separate these segments logically, an explicit branch must be included. The **break** statement, which is actually a restricted goto, is normally used for exiting **switch** statements. **break** transfers control to the first statement after the compound statement in which it appears.

The following **switch** statement uses **break** to restrict each execution to a single selectable segment:

```
switch (index) {
  case 1:
  case 3: odd += 1;
          sumodd += index;
          break;
  case 2:
  case 4: even += 1;
          sumeven += index;
          break;
  default: printf("Error in switch, index = %d\n", index);
}
```

Occasionally, it is convenient to allow control to flow from one selectable code segment to another. For example, in the example above, the segments for the case values 1 and 2 are empty, allowing control to flow to the segments for 3 and 4, respectively. This is the reason why there are no

implicit branches in the **switch** statement. The reliability problem with this design arises when the mistaken absence of a **break** statement in a segment allows control to flow to the next segment incorrectly. The designers of C's **switch** traded a decrease in reliability for an increase in flexibility. Studies have shown, however, that the ability to have control flow from one selectable segment to another is rarely used. C's **switch** is modeled on the multiple-selection statement in ALGOL 68, which also does not have implicit branches from selectable segments.

The C switch statement has virtually no restrictions on the placement of the case expressions, which are treated as if they were normal statement labels. This laxness can result in highly complex structure within the switch body. The following example is taken from Harbison and Steele (2002).

```
switch (x)
  default:
  if (prime(x))
    case 2: case 3: case 5: case 7:
      process_prime(x);
  else
     case 4: case 6: case 8: case 9: case 10:
       process_composite(x);
```

This code may appear to have diabolically complex form, but it was designed for a real problem and works correctly and efficiently to solve that problem.2

2. The problem is to call `process_prime` when `x` is prime and `process_composite` when `x` is not prime. The design of the switch body resulted from an attempt to optimize based on the knowledge that `x` was most often in the range of `1` to `10`.

The Java switch prevents this sort of complexity by disallowing case expressions from appearing anywhere except the top level of the body of the switch.

The C# switch statement differs from that of its C-based predecessors in two ways. First, C# has a static semantics rule that disallows the implicit execution of more than one segment. The rule is that every selectable segment must end with an explicit unconditional branch statement: either a **break**, which transfers control out of the **switch** statement, or a goto, which

can transfer control to one of the selectable segments (or virtually anywhere else). For example,

```
switch (value) {
   case -1:
      Negatives++;
      break;
   case 0:
      Zeros++;
      goto case 1;
   case 1:
      Positives++;
   default:
      Console.WriteLine("Error in switch \n");
}
```

Note that `Console.WriteLine` is the method for displaying strings in C#.

The other way C#'s **`switch`** differs from that of its predecessors is that the control expression and the case statements can be strings in C#.

PHP's **`switch`** uses the syntax of C's **`switch`** but allows more type flexibility. The case values can be any of the PHP scalar types—string, integer, or double precision. As with C, if there is no **`break`** at the end of the selected segment, execution continues into the next segment.

Ruby has two forms of multiple-selection constructs, both of which are called *case expressions* and both of which yield the value of the last expression evaluated. The only version of Ruby's case expressions that is described here is semantically similar to a list of nested if statements:

```
case
when Boolean_expression then expression
. . .
when Boolean_expression then expression
[else expression]
end
```

The semantics of this case expression is that the Boolean expressions are evaluated one at a time, top to bottom. The value of the case expression is the value of the first then expression whose Boolean expression is true. The else represents true in this statement, and the else clause is optional. For

example,[3]

3. This example is from Thomas et al. (2013).

```
leap = case
       when year % 400 == 0 then true
       when year % 100 == 0 then false
       else year % 4 == 0
       end
```

This case expression evaluates to true if `year` is a leap year.

The other Ruby case expression form is similar to the switch of Java. Perl and Python do not have multiple-selection statements.

8.2.2.3 Implementing Multiple Selection Structures

A multiple selection statement is essentially an n-way branch to segments of code, where n is the number of selectable segments. Implementing such a statement must be done with multiple conditional branch instructions. Consider again the general form of the C switch statement, with breaks:

- **switch** (expression) {
- **case** constant_expression1 : statement1;
- **break**;
- . . .
- **case** constantn : statementn;
- **break**;
- [**default** : statementn+1]

- }

One simple translation of this statement follows:

- Code to evaluate expression into t
- **goto** branches
- label1 : code for statement1
- **goto** out
- . . .
- labeln : code for statementn
- **goto** out
- **default**: code for statementn+1
- **goto** out
- branches: **if** t = constant_expression1 **goto** label1
- . . .
- **if** t = constant_expressionn **goto** labeln
- **goto** default
- out:

The code for the selectable segments precedes the branches so that the targets of the branches are all known when the branches are generated. An alternative to these coded conditional branches is to put the case values and labels in a table and use a linear search with a loop to find the correct label. This requires less space than the coded conditionals.

The use of conditional branches or a linear search on a table of cases and

labels is a simple but inefficient approach that is acceptable when the number of cases is small, say less than 10. It takes an average of about half as many tests as there are cases to find the right one. For the default case to be chosen, all other cases must be tested. In statements with 10 or more cases, the low efficiency of this form is not justified by its simplicity.

When the number of cases is 10 or greater, the compiler can build a hash table of the segment labels, which would result in approximately equal (and short) times to choose any of the selectable segments. If the language allows ranges of values for case expressions, as in Ruby, the hash method is not suitable. For these situations, a binary search table of case values and segment addresses is better.

If the range of the case values is relatively small and more than half of the whole range of values is represented, an array whose indices are the case values and whose values are the segment labels can be built. Array elements whose indices are not among the represented case values are filled with the default segment's label. Then finding the correct segment label is found by array indexing, which is very fast.

Of course, choosing among these approaches is an additional burden on the compiler. In many compilers, only two different methods are used. As in other situations, determining and using the most efficient method costs more compiler time.

8.2.2.4 Multiple Selection Using `if`

In many situations, a **`switch`** or **`case`** statement is inadequate for multiple selection (Ruby's **`case`** is an exception). For example, when selections must be made on the basis of a Boolean expression rather than some ordinal type, nested two-way selectors can be used to simulate a multiple selector. To alleviate the poor readability of deeply nested two-way selectors, some languages, such as Perl and Python, have been extended specifically for this use. The extension allows some of the special words to be left out. In particular, else-if sequences are replaced with a single special word, and the closing special word on the nested **`if`** is dropped. The nested selector is then

called an **else-if clause**. Consider the following Python selector statement (note that else-if is spelled **`elif`** in Python):

```
if  count < 10 :
  bag1 = True
elif count < 100 :
  bag2 = True
elif count < 1000 :
  bag3 = True
```

which is equivalent to the following:

```
if count < 10 :
  bag1 = True
else :
  if count < 100 :
    bag2 = True
  else :
    if count < 1000 :
      bag3 = True
    else :
      bag4 = True
```

The else-if version (the first) is the more readable of the two. Notice that this example is not easily simulated with a **`switch`** statement, because each selectable statement is chosen on the basis of a Boolean expression. Therefore, the else-if statement is not a redundant form of **`switch`**. In fact, none of the multiple selectors in contemporary languages are as general as the if-then-else-if statement. An operational semantics description of a general selector statement with else-if clauses, in which the E's are logic expressions and the S's are statements, is given here:

- **if** E1 **goto** 1
- **if** E2 **goto** 2
- . . .
- 1: S1
- **goto** out

- 2: S2
- **goto** out
- . . .
- out: . . .

From this description, we can see the difference between multiple selection structures and else-if statements: In a multiple selection statement, all the E's would be restricted to comparisons between the value of a single expression and some other values.

Languages that do not include the else-if statement can use the same control structure, with only slightly more typing.

The Python example if-then-else-if statement above can be written as the Ruby `case` statement:

```
case
when count < 10 then bag1 = true
when count < 100 then bag2 = true
when count < 1000 then bag3 = true
end
```

Else-if statements are based on the common mathematics statement, the conditional expression.

The Scheme multiple selector, which is based on mathematical conditional expressions, is a special form function named `COND`. `COND` is a slightly generalized version of the mathematical conditional expression; it allows more than one predicate to be true at the same time. Because different mathematical conditional expressions have different numbers of parameters, `COND` does not require a fixed number of actual parameters. Each parameter to `COND` is a pair of expressions in which the first is a predicate (it evaluates to either `#T` or `#F`).

The general form of `COND` is

- `(COND`

- `(` predicate1 expression1`)`
- `(` predicate2 expression2`)`
- . . .
- `(` predicaten expressionn`)`
- `[(ELSE` expressionn+1`)]`
- `)`

where the `ELSE` clause is optional.

The semantics of `COND` is as follows: The predicates of the parameters are evaluated one at a time, in order from the first, until one evaluates to `#T`. The expression that follows the first predicate that is found to be `#T` is then evaluated and its value is returned as the value of `COND`. If none of the predicates is true and there is an `ELSE`, its expression is evaluated and the value is returned. If none of the predicates is true and there is no `ELSE`, the value of `COND` is unspecified. Therefore, all `COND`s should include an `ELSE`.

Consider the following example call to `COND`:

```
(COND
  ((> x y) "x is greater than y")
  ((< x y) "y is greater than x")
  (ELSE "x and y are equal")
)
```

Note that string literals evaluate to themselves, so that when this call to `COND` is evaluated, it produces a string result.

8.3 Iterative Statements

An **iterative statement** is one that causes a statement or collection of statements to be executed zero, one, or more times. An iterative statement is often called a **loop**. Every programming language from Plankalkül on has included some method of repeating the execution of segments of code. Iteration is the very essence of the power of the computer. If some means of repetitive execution of a statement or collection of statements were not possible, programmers would be required to state every action in sequence; useful programs would be huge and inflexible and take unacceptably large amounts of time to write and mammoth amounts of memory to store.

The first iterative statements in programming languages were directly related to arrays. This resulted from the fact that in the earliest years of computers, computing was largely numerical in nature, frequently using loops to process data in arrays.

Several categories of iteration control statements have been developed. The primary categories are defined by how designers answered two basic design questions:

- How is the iteration controlled?
- Where should the control mechanism appear in the loop statement?

The primary possibilities for iteration control are logical, counting, or a combination of the two. The main choices for the location of the control mechanism are the top of the loop or the bottom of the loop. Top and bottom here are logical, rather than physical, denotations. The issue is not the physical placement of the control mechanism; rather, it is whether the mechanism is executed and affects control before or after execution of the statement's body. A third option, which allows the user to decide where to put the control, at the top, at the bottom, or even within the controlled segment, is discussed in Section 8.3.3.

The **body** of an iterative statement is the collection of statements whose execution is controlled by the iteration statement. We use the term **pretest** to mean that the test for loop completion occurs before the loop body is executed and **posttest** to mean that it occurs after the loop body is executed. The iteration statement and the associated loop body together form an **iteration statement**.

8.3.1 Counter-Controlled Loops

A counting iterative control statement has a variable, called the **loop variable**, in which the count value is maintained. It also includes some means of specifying the **initial** and **terminal** values of the loop variable, and the difference between sequential loop variable values, often called the **stepsize**. The initial, terminal, and stepsize specifications of a loop are called the **loop parameters**.

Although logically controlled loops are more general than counter-controlled loops, they are not necessarily more commonly used. Because counter-controlled loops are more complex, their design is more demanding.

Counter-controlled loops are sometimes supported by machine instructions designed for that purpose. Unfortunately, machine architecture can outlive the prevailing approaches to programming at the time of the architecture design. For example, VAX computers have a very convenient instruction for the implementation of posttest counter-controlled loops, which Fortran had at the time of the design of the VAX (mid-1970s). But Fortran no longer had such a loop by the time VAX computers became widely used (it had been replaced by a pretest loop). Furthermore, no other widely used language of the time had a posttest counting loop.

8.3.1.1 Design Issues

There are many design issues for iterative counter-controlled statements. The nature of the loop variable and the loop parameters provide a number of

design issues. The type of the loop variable and that of the loop parameters obviously should be the same or at least compatible, but what types should be allowed? One apparent choice is integer, but what about enumeration, character, and floating-point types? Another question is whether the loop variable is a normal variable, in terms of scope, or whether it should have some special scope. Allowing the user to change the loop variable or the loop parameters within the loop can lead to code that is very difficult to understand, so another question is whether the additional flexibility that might be gained by allowing such changes is worth that additional complexity. A similar question arises about the number of times and the specific time when the loop parameters are evaluated: If they are evaluated just once, loops are simple but less flexible. Finally, what is the value of the loop variable after loop termination, if its scope extends beyond the loop?

The following is a summary of these design issues:

- What are the type and scope of the loop variable?
- Should it be legal for the loop variable or loop parameters to be changed in the loop, and if so, does the change affect loop control?
- Should the loop parameters be evaluated only once, or once for every iteration?
- What is the value of the loop variable after loop termination?

The issue of the value of the loop variable after loop termination is solved in some languages, such as Fortran 90, by making the loop variable undefined after loop termination. Other languages, such as Ada, make the scope of the loop variable the loop itself.

8.3.1.2 The `for` Statement of the C-Based Languages

The general form of C's **`for`** statement is

- `for` (expression_1; expression_2; expression_3)
- loop body

The loop body can be a single statement, a compound statement, or a null statement.

Because assignment statements in C produce results and thus can be considered expressions, the expressions in a `for` statement are often assignment statements. The first expression is for initialization and is evaluated only once, when the `for` statement execution begins. The second expression is the loop control and is evaluated before each execution of the loop body. As is usual in C, a zero value means false and all nonzero values mean true. Therefore, if the value of the second expression is zero, the `for` is terminated; otherwise, the loop body statements are executed. In C99, the expression also could be a Boolean type. A C99 Boolean type stores only the values 0 or 1. The last expression in the `for` is executed after each execution of the loop body. It is often used to increment the loop counter. An operational semantics description of the C `for` statement is shown next. Because C expressions can be used as statements, expression evaluations are shown as statements.

- expression_1
- loop:
- **if** expression_2 = 0 **goto** out
- [loop body]
- expression_3
- **goto** loop
- out: . . .

Following is an example of a skeletal C `for` statement:

```
for (count = 1; count <= 10; count++)
```

```
  . . .
}
```

All of the expressions of C's **`for`** are optional. An absent second expression is considered true, so a **`for`** without one is potentially an infinite loop. If the first and/or third expressions are absent, no assumptions are made. For example, if the first expression is absent, it simply means that no initialization takes place.

Note that C's **`for`** need not count. It can easily model counting *and* logical loop structures, as demonstrated in the next section.

The C **`for`** design choices are the following: There is no explicit loop variable and no loop parameters. All involved variables can be changed in the loop body. The expressions are evaluated in the order stated previously. Although it can create havoc, it is legal to branch into a C **`for`** loop body.

C's **`for`** is one of the most flexible, because each of the expressions can comprise multiple expressions, which in turn allow multiple loop variables that can be of any type. When multiple expressions are used in a single expression of a **`for`** statement, they are separated by commas. All C statements have values, and this form of multiple expression is no exception. The value of such a multiple expression is the value of the last component.

Consider the following **`for`** statement:

```
for (count1 = 0, count2 = 1.0;
    count1 <= 10 && count2 <= 100.0;
    sum = ++count1 + count2, count2 *= 2.5);
```

The operational semantics description of this is

- count1 = 0
- count2 = 1.0
- loop:
- **if** count1 > 10 **goto** out

- **if** count2 > 100.0 **goto** out
- count1 = count1 + 1
- sum = count1 + count2
- count2 = count2 * 2.5
- **goto** loop
- out: . . .

The example C **`for`** statement does not need and thus does not have a loop body. All the desired actions are part of the **`for`** statement itself, rather than in its body. The first and third expressions are multiple statements. In both of these cases, the whole expression is evaluated, but the resulting value is not used in the loop control.

The **`for`** statement of C99 and C++ differs from that of earlier versions of C in two ways. First, in addition to an arithmetic expression, it can use a Boolean expression for loop control. Second, the first expression can include variable definitions. For example,

```
for (int count = 0; count < len; count++) { . . . }
```

The scope of a variable defined in the **`for`** statement is from its definition to the end of the loop body.

The **`for`** statement of Java and C# is like that of C++, except that the loop control expression is restricted to **`boolean`**.

In all of the C-based languages, the last two loop parameters are evaluated with every iteration. Furthermore, variables that appear in the loop parameter expression can be changed in the loop body. Therefore, these loops can be complex and potentially unreliable.

8.3.1.3 The `for` Statement of Python

The general form of Python's **for** is

- **for** loop_variable **in** object:
- - loop body
- [**else**:
- - else clause]

The loop variable is assigned the value in the object, which is often a range, one for each execution of the loop body. After loop termination, the loop variable has the value last assigned to it. The loop variable can be changed in the loop body, but such a change has no effect on loop operation. The else clause, when present, is executed if the loop terminates normally.

Consider the following example:

```
for count in [2, 4, 6]:
   print count
```

produces

```
2
4
6
```

For most simple counting loops in Python, the **range** function is used. **range** takes one, two, or three parameters. The following examples demonstrate the actions of **range**:

```
range(5) returns [0, 1, 2, 3, 4]
range(2, 7) returns [2, 3, 4, 5, 6]
range(0, 8, 2) returns [0, 2, 4, 6]
```

Note that **range** never returns the highest value in a given parameter range.

8.3.1.4 Counter-Controlled Loops in

Functional Languages

Counter-controlled loops in imperative languages use a counter variable, but such variables do not exist in pure functional languages. Rather than iteration to control repetition, functional languages use recursion. Rather than a statement, functional languages use a recursive function. Counting loops can be simulated in functional languages as follows: The counter can be a parameter for a function that repeatedly executes the loop body, which can be specified in a second function sent to the loop function as a parameter. So, such a loop function takes the body function and the number of repetitions as parameters.

The general form of an F# function for simulating counting loops, named `forLoop` in this case, is as follows:

```
let rec forLoop loopBody reps =
    if reps <= 0  then
        ()
    else
         loopBody()
         forLoop loopBody, (reps - 1);;
```

In this function, the parameter `loopBody` is the function with the body of the loop and the parameter `reps` is the number of repetitions. The reserved word **`rec`** appears before the name of the function to indicate that it is recursive. The empty parentheses do nothing; they are there because in F# an empty statement is illegal and every **`if`** must have an else clause.

8.3.2 Logically Controlled Loops

In many cases, collections of statements must be repeatedly executed, but the repetition control is based on a Boolean expression rather than a counter. For these situations, a logically controlled loop is convenient. Actually, logically controlled loops are more general than counter-controlled loops. Every counting loop can be built with a logical loop, but the reverse is not true. Also, recall that only selection and logical loops are essential to express the

control structure of any flowchart.

8.3.2.1 Design Issues

Because they are much simpler than counter-controlled loops, logically controlled loops have fewer design issues.

- Should the control be pretest or posttest?
- Should the logically controlled loop be a special form of a counting loop or a separate statement?

8.3.2.2 Examples

The C-based programming languages include both pretest and posttest logically controlled loops that are not special forms of their counter-controlled iterative statements. The pretest and posttest logical loops have the following forms:

- **`while`** (control_expression)
- loop body

and

- **`do`**
- loop body
- **`while`** (control_expression);

These two statement forms are exemplified by the following C# code segments:

```
sum = 0;
indat = Int32.Parse(Console.ReadLine());
```

```
while (indat >= 0) {
  sum += indat;
  indat = Int32.Parse(Console.ReadLine());
}
value = Int32.Parse(Console.ReadLine());
do {
   value /= 10;
   digits ++;
}  while  (value > 0);
```

Note that all variables in these examples are integer type. The `ReadLine` method of the `Console` object gets a line of text from the keyboard. `Int32.Parse` finds the number in its string parameter, converts it to **`int`** type, and returns it.

In the pretest version of a logical loop (**`while`**), the statement or statement segment is executed as long as the expression evaluates to true. In the posttest version (**`do`**), the loop body is executed until the expression evaluates to false. In both cases, the statement can be compound. The operational semantics descriptions of those two statements follow:

- **`while`**
- loop:
- **`if`** control_expression is false **`goto`** out
- [loop body]
- **`goto`** loop
- out: . . .
- **do-while**
- loop:
- [loop body]
- **`if`** control_expression is true **`goto`** loop

It is legal in both C and C++ to branch into both **`while`** and **`do`** loop bodies. The C89 version uses an arithmetic expression for control; in C99 and C++, it may be either arithmetic or Boolean.

Java's **`while`** and **`do`** statements are similar to those of C and C++, except the control expression must be **`boolean`** type, and because Java does not have a goto, the loop bodies cannot be entered anywhere except at their beginnings.

Posttest loops are infrequently useful and also can be somewhat dangerous, in the sense that programmers sometimes forget that the loop body will always be executed at least once. The syntactic design of placing a posttest control physically after the loop body, where it has its semantic effect, helps avoid such problems by making the logic clear.

A pretest logical loop can be simulated in a purely functional form with a recursive function that is similar to the one used to simulate a counting loop statement in Section 8.3.1.5. In both cases, the loop body is written as a function. Following is the general form of a simulated logical pretest loop, written in F#:

```
let rec whileLoop test body =
    if test() then
        body()
        whileLoop test body
     else
         ();;
```

8.3.3 User-Located Loop Control Mechanisms

In some situations, it is convenient for a programmer to choose a location for loop control other than the top or bottom of the loop body. As a result, some languages provide this capability. A syntactic mechanism for user-located loop control can be relatively simple, so its design is not difficult. Such loops have the structure of infinite loops but include one or more user-located loop exits. Perhaps the most interesting question is whether a single loop or

several nested loops can be exited. The design issues for such a mechanism are the following:

- Should the conditional mechanism be an integral part of the exit?
- Should only one loop body be exited, or can enclosing loops also be exited?

C, C++, Python, Ruby, and C# have unconditional unlabeled exits (**`break`**). Java and Perl have unconditional labeled exits (**`break`** in Java, **`last`** in Perl).

Following is an example of nested loops in Java, in which there is a break out of the outer loop from the nested loop:

```
outerLoop:
  for (row = 0; row < numRows; row++)
     for  (col = 0; col < numCols; col++) {
       sum += mat[row][col];
       if (sum > 1000.0)
         break outerLoop;
     }
```

C, C++, and Python include an unlabeled control statement, **`continue`**, that transfers control to the control mechanism of the smallest enclosing loop. This is not an exit but rather a way to skip the rest of the loop statements on the current iteration without terminating the loop construct. For example, consider the following:

```
while (sum < 1000) {
  getnext(value);
  if (value < 0) continue;
  sum += value;
}
```

A negative value causes the assignment statement to be skipped, and control is transferred instead to the conditional at the top of the loop. On the other hand, in

```
while (sum < 1000) {
  getnext(value);
  if (value < 0) break;
  sum += value;
```

```
}
```

a negative value terminates the loop.

Both **`last`** and **`break`** provide for multiple exits from loops, which may seem to be somewhat of a hindrance to readability. However, unusual conditions that require loop termination are so common that such a statement is justified. Furthermore, readability is not seriously harmed, because the target of all such loop exits is the first statement after the loop (or an enclosing loop) rather than just anywhere in the program. Finally, the alternative of using multiple breaks to leave more than one level of loops is even more detrimental to readability.

The motivation for user-located loop exits is simple: They fulfill a common need for goto statements using a highly restricted branch statement. The target of a goto can be many places in the program, both above and below the goto itself. However, the targets of user-located loop exits must be below the exit and can only follow immediately at the end of a compound statement.

8.3.4 Iteration Based on Data Structures

A general data-based iteration statement uses a user-defined data structure and a user-defined function (the iterator) to go through the structure's elements. The iterator is called at the beginning of each iteration, and each time it is called, the iterator returns an element from a particular data structure in some specific order. For example, suppose a program has a user-defined binary tree of data nodes, and the data in each node must be processed in some particular order. A user-defined iteration statement for the tree would successively set the loop variable to point to the nodes in the tree, one for each iteration. The initial execution of the user-defined iteration statement needs to issue a special call to the iterator to get the first tree element. The iterator must always remember which node it presented last so that it visits all nodes without visiting any node more than once. So an iterator must be history sensitive. A user-defined iteration statement

terminates when the iterator fails to find more elements.

The **`for`** statement of the C-based languages, because of its great flexibility, can be used to simulate a user-defined iteration statement. Once again, suppose the nodes of a binary tree are to be processed. If the tree root is pointed to by a variable named `root`, and if `traverse` is a function that sets its parameter to point to the next element of a tree in the desired order, the following could be used:

```
for (ptr = root; ptr == null; ptr = traverse(ptr)) {
  . . .
}
```

In this statement, `traverse` is the iterator.

User-defined iteration statements are more important in object-oriented programming than they were in earlier software development paradigms, because users of object-oriented programming routinely use abstract data types for data structures, especially collections. In such cases, a user-defined iteration statement and its iterator must be provided by the author of the data abstraction because the representation of the objects of the type is not known to the user.

An enhanced version of the **`for`** statement was added to Java in Java 5.0. This statement simplifies iterating through the values in an array or objects in a collection that implements the `Iterable` interface. (All of the predefined generic collections in Java implement `Iterable`.) For example, if we had an `ArrayList`[4] collection named `myList` of strings, the following statement would iterate through all of its elements, setting each to `myElement`:

4. An `ArrayList` is a predefined generic collection that is actually a dynamic-length array of whatever type it is declared to store.

```
for  (String myElement : myList) { . . . }
```

This new statement is referred to as “foreach,” although its reserved word is **`for`**.

C# and F# (and the other .NET languages) also have generic library classes

for collections. For example, there are generic collection classes for lists, which are dynamic length arrays, stacks, queues, and dictionaries (hash table). All of these predefined generic collections have built-in iterators that are used implicitly with the **`foreach`** statement. Furthermore, users can define their own collections and write their own iterators, which can implement the `IEnumerator` interface, which enables the use of **`foreach`** on these collections.

For example, consider the following C# code:

```
List<String> names =  new  List<String>();
names.Add("Bob");
names.Add("Carol");
names.Add("Alice");
. . .
foreach  (String name  in  names)
  Console.WriteLine(name);
```

In Ruby, a **block** is a sequence of code, delimited by either braces or the **`do`** and **`end`** reserved words. Blocks can be used with specially written methods to create many useful constructs, including iterators for data structures. This construct consists of a method call followed by a block. A block is actually an anonymous method that is sent to the method (whose call precedes it) as a parameter. The called method can then call the block, which can produce output or objects.

Ruby predefines several iterator methods, such as `times` and `upto` for counter-controlled loops, and `each` for simple iterations of arrays and hashes. For example, consider the following example of using `times`:

```
>> 4.times {puts "Hey!"}
Hey!
Hey!
Hey!
Hey!
=> 4
```

Note that `>>` is the prompt of the interactive Ruby interpreter and `=>` is used to indicate the return value of the expression. The Ruby `puts` statement displays its parameter. In this example, the `times` method is sent to the object `4`, with the block sent along as a parameter. The `times` method calls the block

four times, producing the four lines of output. The destination object, `4`, is the return value from `times`.

The most common Ruby iterator is `each`, which is often used to go through arrays and apply a block to each element.5 For this purpose, it is convenient to allow blocks to have parameters, which, if present, appear at the beginning of the block, delimited by vertical bars (|). The following example, which uses a block parameter, illustrates the use of `each`:

5. This is similar to the map functions discussed in Chapter 15.

```
>> list = [2, 4, 6, 8]
=> [2, 4, 6, 8]
>> list.each {|value| puts value}
2
4
6
8
=> [2, 4, 6, 8]
```

In this example, the block is called for each element of the array to which the `each` method is sent. The block produces the output, which is a list of the array's elements. The return value of `each` is the array to which it is sent.

Instead of a counting loop, Ruby has the `upto` method. For example, we could have the following:

```
1.upto(5) {|x| print x, " "}
```

This produces the following output:

```
1 2 3 4 5
```

Syntax that resembles a **`for`** loop in other languages could also be used, as in the following:

```
for x in 1..5
  print x, " "
end
```

Ruby actually has no **`for`** statement—constructs like the above are converted

by Ruby into `upto` method calls.

Now we consider how blocks work. The **`yield`** statement is similar to a method call, except that there is no receiver object and the call is a request to execute the block attached to the method call, rather than a call to a method. **`yield`** is only called in a method that has been called with a block. If the block has parameters, they are specified in parentheses in the **`yield`** statement. The value returned by a block is that of the last expression evaluated in the block. It is this process that is used to implement the built-in iterators, such as `times`.

Python provides strong support for iteration. Suppose one needs to process the nodes in some user-defined data structure. Further suppose that the structure has a traversal method that goes through the nodes of the structure in the desired order. The following skeletal class definition includes such a traversal method that produces the nodes of an instance of this class, one at a time.

```
class MyStructure:
    # Other method definitions, including a constructor
   def traverse(self):
       # if there is another node:
       #    set nod to next node
       # else:
       #    return
       yield nod
```

The `traverse` method appears to be a regular Python method, but it contains a **`yield`** statement, which dramatically changes the semantics of the method. In effect, the method is run in a separate thread of control. The **`yield`** statement acts like a return. On the first call to `traverse`, **`yield`** returns the initial node of the structure. However, on the second call, it returns the second node. On all but the first call to `traverse`, it begins its execution where it left off on the previous execution. Instead of restarting at its beginning, it is resumed. Any local storage in such a method is maintained across its calls. In the case of `traverse`, subsequent calls begin their execution at the beginning of its code, but in the state that it was in its previous execution. In Python, any method that contains a **`yield`** statement is called a *generator*, because it generates data one element at a time.

Of course, one could also produce all of the nodes of the structure, store them in an array, and process them from the array. However, the number of nodes could be large, requiring a large array to store them. The approach using the iterator is more elegant and is not affected by the size of the data structure.

8.4 Unconditional Branching

An **unconditional branch statement** transfers execution control to a specified location in the program. The most heated debate in language design in the late 1960s was over the issue of whether unconditional branching should be part of any high-level language, and if so, whether its use should be restricted. The unconditional branch, or goto, is the most powerful statement for controlling the flow of execution of a program's statements. However, careless use of the goto can lead to serious problems. The goto has stunning power and great flexibility (all other control structures can be built with goto and a selector), but it is this power that makes its use dangerous. Without usage restrictions, imposed by either language design or programming standards, goto statements can make programs very difficult to read, and as a result, highly unreliable and costly to maintain.

history note

Although several thoughtful people had pointed out the potential problems of gotos earlier, it was Edsger Dijkstra who gave the computing world the first widely read exposé on the dangers of the goto. In his letter he noted, "The goto statement as it stands is just too primitive; it is too much an invitation to make a mess of one's program" (Dijkstra, 1968a). During the first few years after publication of Dijkstra's views on the goto, a large number of people argued publicly for either outright banishment or at least restrictions on the use of the goto. Among those who did not favor complete elimination was Donald Knuth (1974), who argued that there were occasions when the efficiency of the goto outweighed its harm to readability.

These problems follow directly from a goto's ability to force any program statement to follow any other in execution sequence, regardless of whether that statement precedes or follows the previously executed statement in textual order. Readability is best when the execution order of statements in a program is nearly the same as the order in which they appear—in our case,

this would mean top to bottom, which is the order to which we are accustomed. Thus, restricting gotos so they can transfer control only downward in a program partially alleviates the problem. It allows gotos to transfer control around code sections in response to errors or unusual conditions but disallows their use to build any sort of loop.

A few languages have been designed without a goto—for example, Java, Python, and Ruby. However, most currently popular languages include a goto statement. Kernighan and Ritchie (1978) call the goto infinitely abusable, but it is nevertheless included in Ritchie's language, C. The languages that have eliminated the goto have provided additional control statements, usually in the form of loop exits, to code one of the justifiable applications of the goto.

The relatively new language, C#, includes a goto, even though one of the languages on which it is based, Java, does not. One legitimate use of C#'s goto is in the `switch` statement, as discussed in Section 8.2.2.2.

All of the loop exit statements discussed in Section 8.3.3 are actually camouflaged goto statements. They are, however, severely restricted gotos and are not harmful to readability. In fact, it can be argued that they improve readability, because to avoid their use results in convoluted and unnatural code that would be much more difficult to understand.

8.5 Guarded Commands

Quite different forms of selection and loop structures were suggested by Dijkstra (1975). His primary motivation was to provide control statements that would support a program design methodology that ensured correctness during development rather than when verifying or testing completed programs. This methodology is described in Dijkstra (1976). Another motivation is the increased clarity in reasoning that is possible with guarded commands. Simply put, a selectable segment of a selection statement in a guarded-command statement can be considered independently of any other part of the statement, which is not true for the selection statements of the common programming languages.

Guarded commands are covered in this chapter because they are the basis for the linguistic mechanism developed later for concurrent programming in CSP (Hoare, 1978). Guarded commands are also used to define functions in Haskell, as discussed in Chapter 15.

Dijkstra's selection statement has the form

- **`if`** <Boolean expression> `->` <statement>
- `[]` <Boolean expression> `->` <statement>
- `[] . . .`
- `[]` <Boolean expression> `->` <statement>
- **`fi`**

The closing reserved word, **`fi`**, is the opening reserved word spelled backward. This form of closing reserved word is taken from ALGOL 68. The small blocks, called *fatbars*, are used to separate the guarded clauses and allow the clauses to be statement sequences. Each line in the selection statement, consisting of a Boolean expression (a guard) and a statement or statement sequence, is called a **guarded command**.

This selection statement has the appearance of a multiple selection, but its semantics is different. All of the Boolean expressions are evaluated each time the statement is reached during execution. If more than one expression is true, one of the corresponding statements can be nondeterministically chosen for execution. An implementation might always choose the statement associated with the first Boolean expression that evaluates to be true. But it may choose any statement associated with a true Boolean expression. So, the correctness of the program cannot depend on which statement is chosen (among those associated with true Boolean expressions). If none of the Boolean expressions are true, a run-time error occurs that causes program termination. This forces the programmer to consider and list all possibilities. Consider the following example:

```
if i = 0 -> sum := sum + i
[] i > j -> sum := sum + j
[] j > i -> sum := sum + k
fi
```

If `i = 0` and `j > i`, this statement chooses nondeterministically between the first and third assignment statements. If `i` is equal to `j` and is not zero, a run-time error occurs because none of the conditions are true.

This statement can be an elegant way of allowing the programmer to state that the order of execution, in some cases, is irrelevant. For example, to find the largest of two numbers, we can use

```
if  x >= y -> max := x
[] y >= x -> max := y
fi
```

This computes the desired result without overspecifying the solution. In particular, if `x` and `y` are equal, it does not matter which we assign to `max`. This is a form of abstraction provided by the nondeterministic semantics of the statement.

Now, consider this same process coded in a traditional programming language selector:

```
if (x >= y)
  max = x;
```

```
else
  max = y;
```

This could also be coded as follows:

```
if (x > y)
  max = x;
else
  max = y;
```

There is no practical difference between these two statements. The first assigns `x` to `max` when `x` and `y` are equal; the second assigns `y` to `max` in the same circumstance. This choice between the two statements complicates the formal analysis of the code and the correctness proof of it. This is one of the reasons why guarded commands were developed by Dijkstra.

The loop structure proposed by Dijkstra has the form

- **`do`** <Boolean expression> `->` <statement>
- `[]` <Boolean expression> `->` <statement>
- `[] . . .`
- `[]` <Boolean expression> `->` <statement>
- **`od`**

The semantics of this statement is that all Boolean expressions are evaluated on each iteration. If more than one is true, one of the associated statements is nondeterministically (perhaps randomly) chosen for execution, after which the expressions are again evaluated. When all expressions are simultaneously false, the loop terminates.

Consider the following problem: Given four integer variables, `q1`, `q2`, `q3`, and `q4`, rearrange the values of the four so that `q1 <= q2 <= q3 <= q4`. Without guarded commands, one straightforward solution is to put the four values into an array, sort the array, and then assign the values from the array back into the scalar variables `q1`, `q2`, `q3`, and `q4`. While this solution is not difficult, it requires a good deal of code, especially if the sort process must be included.

Now, consider the following code, which uses guarded commands to solve the same problem but in a more concise and elegant way.6

6. This code appears in a slightly different form in Dijkstra (1975).

```
do q1 > q2 -> temp := q1; q1 := q2; q2 := temp;
[] q2 > q3 -> temp := q2; q2 := q3; q3 := temp;
[] q3 > q4 -> temp := q3; q3 := q4; q4 := temp;
od
```

Dijkstra's guarded command control statements are interesting, in part because they illustrate how the syntax and semantics of statements can have an impact on program verification and vice versa. Program verification is virtually impossible when goto statements are used. Verification is greatly simplified if (1) only logical loops and selections are used or (2) only guarded commands are used. The axiomatic semantics of guarded commands are conveniently specified (Gries, 1981). It should be obvious, however, that there is considerably increased complexity in the implementation of the guarded commands over their conventional deterministic counterparts.

8.6 Conclusions

We have described and discussed a variety of statement-level control structures. A brief evaluation now seems to be in order.

First, we have the theoretical result that only sequence, selection, and pretest logical loops are absolutely required to express computations (Böhm and Jacopini, 1966). This result has been used by those who wish to ban unconditional branching altogether. Of course, there are already sufficient practical problems with the goto to condemn it without also using a theoretical reason. One of the main legitimate needs for gotos—premature exits from loops—can be met with restricted branch statements, such as `break`.

One obvious misuse of the Böhm and Jacopini result is to argue against the inclusion of *any* control structures beyond selection and pretest logical loops. No widely used language has yet taken that step; furthermore, we doubt that any ever will, because of the negative effect on writability and readability. Programs written with only selection and pretest logical loops are generally less natural in structure, more complex, and therefore harder to write and more difficult to read. For example, the C# multiple selection structure is a great boost to C# writability, with no obvious negatives. Another example is the counting loop structure of many languages, especially when the statement is simple.

It is not so clear that the utility of many of the other control structures that have been proposed is worth their inclusion in languages (Ledgard and Marcotty, 1975). This question rests to a large degree on the fundamental question of whether the size of languages must be minimized. Both Wirth (1975) and Hoare (1973) strongly endorse simplicity in language design. In the case of control structures, simplicity means that only a few control statements should be in a language, and they should be simple.

The rich variety of statement-level control structures that have been invented shows the diversity of opinion among language designers. After all the

invention, discussion, and evaluation, there is still no unanimity of opinion on the precise set of control statements that should be in a language. Most contemporary languages do, of course, have similar control statements, but there is still some variation in the details of their syntax and semantics. Furthermore, there is still disagreement on whether a language should include a goto; C++ and C# do, but Java and Ruby do not.

SUMMARY

Control statements occur in several categories: selection, multiple selection, iterative, and unconditional branching.

The `switch` statement of the C-based languages is representative of multiple-selection statements. The C# version eliminates the reliability problem of its predecessors by disallowing the implicit continuation from a selected segment to the following selectable segment.

A large number of different loop statements have been invented for high-level languages. C's `for` statement is the most flexible iteration statement, although its flexibility leads to some reliability problems.

Most languages have exit statements for their loops; these statements take the place of one of the most common uses of goto statements.

Data-based iterators are loop statements for processing data structures, such as linked lists, hashes, and trees. The `for` statement of the C-based languages allows the user to create iterators for user-defined data. The `foreach` statement of Perl and C# is a predefined iterator for standard data structures. In the contemporary object-oriented languages, iterators for collections are specified with standard interfaces, which are implemented by the designers of the collections.

Ruby includes iterators that are a special form of methods that are sent to various objects. The language predefines iterators for common uses, but also allows user-defined iterators.

The unconditional branch, or goto, has been part of most imperative languages. Its problems have been widely discussed and debated. The current consensus is that it should remain in most languages but that its dangers should be minimized through programming discipline.

Dijkstra's guarded commands are alternative control statements with positive theoretical characteristics. Although they have not been adopted as the

control statements of a language, part of the semantics appear in the concurrency mechanisms of CSP and the function definitions of Haskell.

REVIEW QUESTIONS

1. What is the definition of *control structure?*
2. What did Böhm and Jocopini prove about flowcharts?
3. What is the definition of *block?*
4. What is/are the design issue(s) for all selection and iteration control statements?
5. What are the design issues for selection structures?
6. What is unusual about Python's design of compound statements?
7. Under what circumstances must an F# selector have an else clause?
8. What are the common solutions to the nesting problem for two-way selectors?
9. What are the design issues for multiple-selection statements?
10. Between what two language characteristics is a trade-off made when deciding whether more than one selectable segment is executed in one execution of a multiple selection statement?
11. What is unusual about C's multiple-selection statement?
12. On what previous language was C's **`switch`** statement based?
13. Explain how C#'s switch statement is safer than that of C.
14. What are the design issues for all iterative control statements?
15. What are the design issues for counter-controlled loop statements?
16. What is a pretest loop statement? What is a posttest loop statement?

17. What is the difference between the **`for`** statement of C++ and that of Java?

18. In what way is C's **`for`** statement more flexible than that of many other languages?

19. What does the **`range`** function in Python do?

20. What contemporary languages do not include a goto?

21. What are the design issues for logically controlled loop statements?

22. What is the main reason user-located loop control statements were invented?

23. What are the design issues for user-located loop control mechanisms?

24. What advantage does Java's **`break`** statement have over C's **`break`** statement?

25. What are the differences between the **`break`** statement of C++ and that of Java?

26. What is a user-defined iteration control?

27. What Scheme function implements a multiple selection statement?

28. How does a functional language implement repetition?

29. How are iterators implemented in Ruby?

30. What language predefines iterators that can be explicitly called to iterate over its predefined data structures?

31. What common programming language borrows part of its design from Dijkstra's guarded commands?

PROBLEM SET

1. Describe three situations where a combined counting and logical looping statement is needed.

2. Study the iterator feature of CLU in Liskov et al. (1981) and determine its advantages and disadvantages.

3. Compare the set of Ada control statements with those of C# and decide which are better and why.

4. What are the pros and cons of using unique closing reserved words on compound statements?

5. What are the arguments, pros and cons, for Python's use of indentation to specify compound statements in control statements?

6. Analyze the potential readability problems with using closure reserved words for control statements that are the reverse of the corresponding initial reserved words, such as the **`case-esac`** reserved words of ALGOL 68. For example, consider common typing errors such as transposing characters.

7. Use the *Science Citation Index* to find an article that refers to Knuth (1974). Read the article and Knuth's paper and write a paper that summarizes both sides of the goto issue.

8. In his paper on the goto issue, Knuth (1974) suggests a loop control statement that allows multiple exits. Read the paper and write an operational semantics description of the statement.

9. What are the arguments both for and against the exclusive use of Boolean expressions in the control statements in Java (as opposed to also allowing arithmetic expressions, as in C++)?

10. Describe a programming situation in which the else clause in Python's

`for` statement would be convenient.

11. Describe three specific programming situations that require a posttest loop.

12. Speculate as to the reason control can be transferred into a C loop statement.

PROGRAMMING EXERCISES

1. Rewrite the following pseudocode segment using a loop structure in the specified languages:

```
  k = (j + 13) / 27
loop:
  if k > 10 then goto  out
  k = k + 1
  i = 3 * k - 1
  goto  loop
out: . . .
```

   1. C, C++, Java, or C#

   2. Python

   3. Ruby

   Assume all variables are integer type. Discuss which language, for this code, has the best writability, the best readability, and the best combination of the two.

2. Redo Programming Exercise 1, except this time make all the variables and constants floating-point type, and change the statement

   ```
   k = k + 1
   ```

   to

   ```
   k = k + 1.2
   ```

3. Rewrite the following code segment using a multiple-selection statement in the following languages:

```
if ((k == 1) || (k == 2)) j = 2 * k - 1
if ((k == 3) || (k == 5)) j = 3 * k + 1
if (k == 4) j = 4 * k - 1
if ((k == 6) || (k == 7) || (k == 8)) j = k - 2
```

1. C, C++, Java, or C#

2. Python

3. Ruby

Assume all variables are integer type. Discuss the relative merits of the use of these languages for this particular code.

4. Consider the following C program segment. Rewrite it using no gotos or **`break`**s.

```
j = -3;
for (i = 0; i < 3; i++) {
  switch  (j + 2) {
    case  3:
    case  2: j--; break;
    case  0: j += 2; break;
    default: j = 0;
  }
  if  (j > 0)  break;
 j = 3 - i
}
```

5. In a letter to the editor of *CACM*, Rubin (1987) uses the following code segment as evidence that the readability of some code with gotos is better than the equivalent code without gotos. This code finds the first row of an *n* by *n* integer matrix named `x` that has nothing but zero values.

```
for (i = 1; i <= n; i++) {
  for (j = 1; j <= n; j++)
    if (x[i][j] != 0)
     goto reject;
  println ('First all-zero row is:', i);
  break;
reject:
 }
```

Rewrite this code without gotos in one of the following languages: C, C++, Java, or C#. Compare the readability of your code to that of the example code.

6. Consider the following programming problem: The values of three integer variables—`first`, `second`, and `third`–must be placed in the three variables `max`, `mid`, and `min`, with the obvious meanings, without using arrays or user-defined or predefined subprograms. Write two solutions to this problem, one that uses nested selections and one that does not. Compare the complexity and expected reliability of the two.

7. Rewrite the C program segment of Programming Exercise 4 using **`if`** and goto statements in C.

8. Rewrite the C program segment of Programming Exercise 4 in Java without using a **`switch`** statement.

9. Translate the following call to Scheme's `COND` to C and set the resulting value to `y`.

```
(COND
 ((> x 10) x)
 ((< x 5) (* 2 x))
 ((= x 7) (+ x 10))
)
```

9 Subprograms

Subprograms are the fundamental building blocks of programs and are therefore among the most important concepts in programming language design. We now explore the design of subprograms, including parameter-passing methods, local referencing environments, overloaded subprograms, generic subprograms, and the aliasing and problematic side effects that are associated with subprograms. We also include discussions of indirectly called subprograms, closures, and coroutines.

Implementation methods for subprograms are discussed in Chapter 10.

9.1 Introduction

Two fundamental abstraction facilities can be included in a programming language: process abstraction and data abstraction. In the early history of high-level programming languages, only process abstraction was included. Process abstraction, in the form of subprograms, has been a central concept in all programming languages. In the 1980s, however, many people began to believe that data abstraction was equally important. Data abstraction is discussed in detail in Chapter 11.

The first programmable computer, Babbage's Analytical Engine, built in the 1840s, had the capability of reusing collections of instruction cards at several different places in a program. In a modern programming language, such a collection of statements is written as a subprogram. This reuse results in savings in memory space and coding time. Such reuse is also an abstraction, for the details of the subprogram's computation are replaced in a program by a statement that calls the subprogram. Instead of describing how some computation is to be done in a program, that description (the collection of statements in the subprogram) is enacted by a call statement, effectively abstracting away the details. This increases the readability of a program by emphasizing its logical structure while hiding its low-level details.

The methods of object-oriented languages are closely related to the subprograms discussed in this chapter. The primary way methods differ from subprograms is the way they are called and their associations with classes and objects. Although these special characteristics of methods are discussed in Chapter 12, the features they share with subprograms, such as parameters and local variables, are discussed in this chapter.

9.2 Fundamentals of Subprograms

9.2.1 General Subprogram Characteristics

All subprograms discussed in this chapter, except the coroutines described in Section 9.13, have the following characteristics:

- Each subprogram has a single entry point.
- The calling program unit is suspended during the execution of the called subprogram, which implies that there is only one subprogram in execution at any given time.
- Control always returns to the caller when the subprogram execution terminates.

Alternatives to these result in coroutines and concurrent units (Chapter 13).

Most subprograms have names, although some are anonymous. Section 9.12 has examples of anonymous subprograms in C#.

9.2.2 Basic Definitions

A **subprogram definition** describes the interface to and the actions of the subprogram abstraction. A **subprogram call** is the explicit request that a specific subprogram be executed. A subprogram is said to be **active** if, after having been called, it has begun execution but has not yet completed that execution. The two fundamental kinds of subprograms, procedures and functions, are defined and discussed in Section 9.2.4.

A **subprogram header**, which is the first part of the definition, serves

several purposes. First, it specifies that the following syntactic unit is a subprogram definition of some particular kind.1 In languages that have more than one kind of subprogram, the kind of the subprogram is usually specified with a special word. Second, if the subprogram is not anonymous, the header provides a name for the subprogram. Third, it may specify a list of parameters.

1. Some programming languages include both kinds of subprograms, procedures and functions.

Consider the following header examples:

```
def adder parameters):
```

This is the header of a Python subprogram named `adder`. Ruby subprogram headers also begin with **`def`**. The header of a JavaScript subprogram begins with **`function`**.

In C, the header of a function named **`adder`** might be as follows:

- `void adder (parameters)`

The reserved word **`void`** in this header indicates that the subprogram does not return a value.

The body of subprograms defines its actions. In the C-based languages (and some others—for example, JavaScript) the body of a subprogram is delimited by braces. In Ruby, an **`end`** statement terminates the body of a subprogram. As with compound statements, the statements in the body of a Python function must be indented and the end of the body is indicated by the first statement that is not indented.

One characteristic of Python functions that sets them apart from the functions of other common programming languages is that function **`def`** statements are executable. When a **`def`** statement is executed, it assigns the given name to the given function body. Until a function's **`def`** has been executed, the function cannot be called. Consider the following skeletal example:

```
if . . .
```

```
  def fun( . . . ):
    . . .
else
  def fun( . . . ):
    . . .
```

If the then clause of this selection construct is executed, that version of the function `fun` can be called, but not the version in the else clause. Likewise, if the else clause is chosen, its version of the function can be called but the one in the then clause cannot.

Ruby methods differ from the subprograms of other programming languages in several interesting ways. Ruby methods are often defined in class definitions but can also be defined outside class definitions, in which case they are considered methods of the root object, `Object`. Such methods can be called without an object receiver, as if they were functions in C or C++. If a Ruby method is called without a receiver, **`self`** is assumed. If there is no method by that name in the class, enclosing classes are searched, up to `Object`, if necessary.

The **parameter profile** of a subprogram contains the number, order, and types of its formal parameters. The **protocol** of a subprogram is its parameter profile plus, if it is a function, its return type. In languages in which subprograms have types, those types are defined by the subprogram's protocol.

Subprograms can have declarations as well as definitions. This form parallels the variable declarations and definitions in C, in which declarations are used to provide type information but not to define variables. Subprogram declarations provide the subprogram's protocol but do not include their bodies. They are necessary in languages that do not allow forward references to subprograms. In both the cases of variables and subprograms, declarations are needed for static type checking. In the case of subprograms, it is the type of the parameters that must be checked. Function declarations are common in C and C++ programs, where they are called **prototypes**. Such declarations are often placed in header files.

In most other languages (other than C and C++), subprograms do not need declarations, because there is no requirement that subprograms be defined

before they are called.

9.2.3 Parameters

Subprograms typically describe computations. There are two ways that a nonmethod subprogram can gain access to the data that it is to process: through direct access to nonlocal variables (declared elsewhere but visible in the subprogram) or through parameter passing. Data passed through parameters are accessed using names that are local to the subprogram. Parameter passing is more flexible than direct access to nonlocal variables. In essence, a subprogram with parameter access to the data that it is to process is a parameterized computation. It can perform its computation on whatever data it receives through its parameters (presuming the types of the parameters are as expected by the subprogram). If data access is through nonlocal variables, the only way the computation can proceed on different data is to assign new values to those nonlocal variables between calls to the subprogram. Extensive access to nonlocals can reduce reliability. Variables that are visible to the subprogram where access is desired often end up also being visible where access to them is not needed. This problem was discussed in Chapter 5.

Although methods also access external data through nonlocal references and parameters, the primary data to be processed by a method is the object through which the method is called. However, when a method does access nonlocal data, the reliability problems are the same as with nonmethod subprograms. Also, in an object-oriented language, method access to class variables (those associated with the class, rather than an object) is related to the concept of nonlocal data and should be avoided whenever possible. In this case, as well as the case of a C function accessing nonlocal data, the method can have the side effect of changing something other than its parameters or local data. Such changes complicate the semantics of the method and make it less reliable.

Pure functional programming languages, such as Haskell, do not have mutable data, so functions written in them are unable to change memory in any way—they simply perform calculations and return a resulting value (or

function, since functions are values in a pure functional language).

In some situations, it is convenient to be able to transmit computations, rather than data, as parameters to subprograms. In these cases, the name of the subprogram that implements that computation may be used as a parameter. This form of parameter is discussed in Section 9.6. Data parameters are discussed in Section 9.5.

The parameters in the subprogram header are called **formal parameters**. They are sometimes thought of as dummy variables because they are not variables in the usual sense: In most cases, they are bound to storage only when the subprogram is called, and that binding is often through some other program variables.

Subprogram call statements must include the name of the subprogram and a list of parameters to be bound to the formal parameters of the subprogram. These parameters are called **actual parameters**.2 They must be distinguished from formal parameters, because the two usually have different restrictions on their forms, and of course, their uses are quite different.

2. Some authors call actual parameters *arguments* and formal parameters just *parameters*.

In most programming languages, the correspondence between actual and formal parameters—or the binding of actual parameters to formal parameters—is done by position: The first actual parameter is bound to the first formal parameter and so forth. Such parameters are called **positional parameters**. This is an effective and safe method of relating actual parameters to their corresponding formal parameters, as long as the parameter lists are relatively short.

When parameter lists are long, however, it is easy for a programmer to make mistakes in the order of actual parameters in the list. One solution to this problem is to provide **keyword parameters**, in which the name of the formal parameter to which an actual parameter is to be bound is specified with the actual parameter in a call. The advantage of keyword parameters is that they can appear in any order in the actual parameter list. Python functions can be called using this technique, as in

```
sumer(length = my_length,
      list = my_array,
      sum = my_sum)
```

where the definition of `sumer` has the formal parameters `length`, `list`, and `sum`.

The disadvantage to keyword parameters is that the user of the subprogram must know the names of formal parameters.

In addition to keyword parameters, some languages, for example Python, allow positional parameters. Keyword and positional parameters can be mixed in a call, as in

```
sumer(my_length,
      sum = my_sum,
      list = my_array)
```

The only restriction with this approach is that after a keyword parameter appears in the list, all remaining parameters must be keyworded. This restriction is necessary because a position may no longer be well defined after a keyword parameter has appeared.

In Python, Ruby, C++, and PHP, formal parameters can have default values. A default value is used if no actual parameter is passed to the formal parameter in the subprogram header. Consider the following Python function header:

```
def compute_pay(income, exemptions = 1, tax_rate)
```

The `exemptions` formal parameter can be absent in a call to `compute_pay`; when it is, the value `1` is used. No comma is included for an absent actual parameter in a Python call, because the only value of such a comma would be to indicate the position of the next parameter, which in this case is not necessary because all actual parameters after an absent actual parameter must be keyworded. For example, consider the following call:

```
pay = compute_pay(20000.0, tax_rate = 0.15)
```

In C++, which does not support keyword parameters, the rules for default

parameters are necessarily different. The default parameters must appear last, because parameters are positionally associated. Once a default parameter is omitted in a call, all remaining formal parameters must have default values. A C++ function header for the `compute_pay` function can be written as follows:

```
float compute_pay(float income, float tax_rate,
                  int exemptions = 1)
```

Notice that the parameters are rearranged so that the one with the default value is last. An example call to the C++ `compute_pay` function is

```
pay = compute_pay(20000.0, 0.15);
```

In most languages that do not have default values for formal parameters, the number of actual parameters in a call must match the number of formal parameters in the subprogram definition header. However, in C, C++, Perl, and JavaScript, this is not required. When there are fewer actual parameters in a call than formal parameters in a function definition, it is the programmer's responsibility to ensure that the parameter correspondence, which is always positional, and the subprogram execution are sensible.

Although this design, which allows a variable number of parameters, is clearly prone to error, it is also sometimes convenient. For example, the `printf` function of C can print any number of items (data values and/or literals).

C# allows methods to accept a variable number of parameters, as long as they are of the same type. The method specifies its formal parameter with the **`params`** modifier. The call can send either an array or a list of expressions, whose values are placed in an array by the compiler and provided to the called method. For example, consider the following method:

```
public void DisplayList(params int[] list) {
   foreach (int next in list) {
      Console.WriteLine("Next value {0}", next);
   }
}
```

If `DisplayList` is defined for the class `MyClass` and we have the following declarations,

```
Myclass myObject = new Myclass;
int[] myList = new int[6] {2, 4, 6, 8, 10, 12};
```

`DisplayList` could be called with either of the following:

```
myObject.DisplayList(myList);
myObject.DisplayList(2, 4, 3 * x - 1, 17);
```

Ruby supports a complicated but highly flexible actual parameter configuration. The initial parameters are expressions, whose value objects are passed to the corresponding formal parameters. The initial parameters can be followed by a list of key => value pairs, which are placed in an anonymous hash and a reference to that hash is passed to the next formal parameter. These are used as a substitute for keyword parameters, which Ruby does not support. The hash item can be followed by a single parameter preceded by an asterisk. This parameter is called the *array formal parameter*. When the method is called, the array formal parameter is set to reference a new `Array` object. All remaining actual parameters are assigned to the elements of the new `Array` object. If the actual parameter that corresponds to the array formal parameter is an array, it must also be preceded by an asterisk, and it must be the last actual parameter.3 So, Ruby allows a variable number of parameters in a way similar to that of C#. Because Ruby arrays can store different types, there is no requirement that the actual parameters passed to the array have the same type.

3. Not quite true, because the array formal parameter can be followed by a method or function reference, which is preceded by an ampersand (&).

The following example skeletal function definition and call illustrate the parameter structure of Ruby:

```
list = [2, 4, 6, 8]
def tester(p1, p2, p3, *p4)
  . . .
end  . . .
tester('first', mon => 72, tue => 68, wed => 59, *list)
```

Inside `tester`, the values of its formal parameters are as follows:

```
p1 is 'first'
p2 is {mon => 72, tue => 68, wed => 59}
```

```
p3 is 2
p4 is [4, 6, 8]
```

Python supports parameters that are similar to those of Ruby.

9.2.4 Procedures and Functions

There are two distinct categories of subprograms—procedures and functions—both of which can be viewed as approaches to extending the language. Subprograms are collections of statements that define parameterized computations. Functions return values and procedures do not. In most languages that do not include procedures as a separate form of subprogram, functions can be defined not to return values and they can be used as procedures. The computations of a procedure are enacted by single call statements. In effect, procedures define new statements. For example, if a particular language does not have a sort statement, a user can build a procedure to sort arrays of data and use a call to that procedure in place of the unavailable sort statement. Only some older languages, such as Fortran and Ada, support procedures.

Procedures can produce results in the calling program unit by two methods: (1) If there are variables that are not formal parameters but are still visible in both the procedure and the calling program unit, the procedure can change them; and (2) if the procedure has formal parameters that allow the transfer of data to the caller, those parameters can be changed.

Functions structurally resemble procedures but are semantically modeled on mathematical functions. If a function is a faithful model, it produces no side effects; that is, it modifies neither its parameters nor any variables defined outside the function. Such a function returns a value—that is its only desired effect. The functions in most programming languages have side effects.

Functions are called by appearances of their names in expressions, along with the required actual parameters. The value produced by a function's execution is returned to the calling code, effectively replacing the call itself. For example, the value of the expression `f(x)` is whatever value `f` produces when called with the parameter `x`. For a function that does not produce side effects,

the returned value is its only effect.

Functions define new user-defined operators. For example, if a language does not have an exponentiation operator, a function can be written that returns the value of one of its parameters raised to the power of another parameter. Its header in C++ could be

```
float power(float base, float exp)
```

which could be called with

```
result = 3.4 * power(10.0, x)
```

The standard C++ library includes a similar function named `pow`. Compare this with the same operation in Perl, in which exponentiation is a built-in operation:

```
result = 3.4 * 10.0 ** x
```

In some programming languages, users are permitted to overload operators by defining new functions for operators. User-defined overloaded operators are discussed in Section 9.11.

9.3 Design Issues for Subprograms

Subprograms are complex structures, and it follows from this that a lengthy list of issues is involved in their design. One obvious issue is the choice of one or more parameter-passing methods that will be used. The wide variety of approaches that have been used in various languages is a reflection of the diversity of opinion on the subject. A closely related issue is whether the types of actual parameters will be type checked against the types of the corresponding formal parameters.

The nature of the local environment of a subprogram dictates to some degree the nature of the subprogram. The most important question here is whether local variables are statically or dynamically allocated.

Next, there is the question of whether subprogram definitions can be nested. Another issue is whether subprogram names can be passed as parameters. If subprogram names can be passed as parameters and the language allows subprograms to be nested, there is the question of the correct referencing environment of a subprogram that has been passed as a parameter.

As seen in Chapter 5, side effects of functions can cause problems. So, restrictions on side effects are a design issue for functions. The types and number of values that can be returned from functions are other design issues.

Finally, there are the questions of whether subprograms can be overloaded or generic. An **overloaded subprogram** is one that has the same name as another subprogram in the same referencing environment. A **generic subprogram** is one whose computation can be done on data of different types in different calls. A **closure** is a nested subprogram and its referencing environment, which together allow the subprogram to be called from anywhere in a program.

The following is a summary of these design issues for subprograms in general. Additional issues that are specifically associated with functions are discussed in Section 9.10.

- Are local variables statically or dynamically allocated?
- Can subprogram definitions appear in other subprogram definitions?
- What parameter-passing method or methods are used?
- Are the types of the actual parameters checked against the types of the formal parameters?
- If subprograms can be passed as parameters and subprograms can be nested, what is the referencing environment of a passed subprogram?
- Are functional side effects allowed?
- What types of values can be returned from functions?
- How many values can be returned from functions?
- Can subprograms be overloaded?
- Can subprograms be generic?
- If the language allows nested subprograms, are closures supported?

These issues and example designs are discussed in the following sections.

9.4 Local Referencing Environments

This section discusses the issues related to variables that are defined within subprograms. The issue of nested subprogram definitions is also briefly covered.

9.4.1 Local Variables

Subprograms can define their own variables, thereby defining local referencing environments. Variables that are defined inside subprograms are called **local variables**, because their scope is usually the body of the subprogram in which they are defined.

In the terminology of Chapter 5, local variables can be either static or stack dynamic. If local variables are stack dynamic, they are bound to storage when the subprogram begins execution and are unbound from storage when that execution terminates. There are several advantages of stack-dynamic local variables, the primary one being flexibility. It is essential that recursive subprograms have stack-dynamic local variables. Another advantage of stack-dynamic locals is that the storage for local variables in an active subprogram can be shared with the local variables in all inactive subprograms. This is not as important an advantage as it was when computers had smaller memories.

The main disadvantages of stack-dynamic local variables are the following: First, there is the cost of the time required to allocate, initialize (when necessary), and deallocate such variables for each call to the subprogram. Second, accesses to stack-dynamic local variables must be indirect, whereas accesses to static variables can be direct.[4] This indirectness is required because the place in the stack where a particular local variable will reside can be determined only during execution (see Chapter 10). Finally, when all local

variables are stack dynamic, subprograms cannot be history sensitive; that is, they cannot retain data values of local variables between calls. It is sometimes convenient to be able to write history-sensitive subprograms. A common example of a need for a history-sensitive subprogram is one whose task is to generate pseudorandom numbers. Each call to such a subprogram computes one pseudorandom number, using the last one it computed. It must, therefore, store the last one in a static local variable. Coroutines and the subprograms used in iterator loop constructs (discussed in Chapter 8) are other examples of subprograms that need to be history sensitive.

4. In some implementations, static variables are also accessed indirectly, thereby eliminating this disadvantage.

The primary advantage of static local variables over stack-dynamic local variables is that they are slightly more efficient—they require no run-time overhead for allocation and deallocation. Also, if accessed directly, these accesses are obviously more efficient. And, of course, they allow subprograms to be history sensitive. The greatest disadvantage of static local variables is their inability to support recursion. Also, their storage cannot be shared with the local variables of other inactive subprograms.

In most contemporary languages, local variables in a subprogram are by default stack dynamic. In C and C++ functions, locals are stack dynamic unless specifically declared to be **`static`**. For example, in the following C (or C++) function, the variable `sum` is static and `count` is stack dynamic.

```
int adder(int list[], int listlen) {
  static int sum = 0;
  int count;
  for (count = 0; count < listlen; count ++)
    sum += list [count];
  return  sum;
}
```

The methods of C++, Java, and C# have only stack-dynamic local variables.

In Python, the only declarations used in method definitions are for globals. Any variable declared to be global in a method must be a variable defined outside the method. A variable defined outside the method can be referenced

in the method without declaring it to be global, but such a variable cannot be assigned in the method. If the name of a global variable is assigned in a method, it is implicitly declared to be a local and the assignment does not disturb the global. All local variables in Python methods are stack dynamic.

9.4.2 Nested Subprograms

The idea of nesting subprograms originated with ALGOL 60. The motivation was to be able to create a hierarchy of both logic and scopes. If a subprogram is needed only within another subprogram, why not place it there and hide it from the rest of the program? Because static scoping is usually used in languages that allow subprograms to be nested, this also provides a highly structured way to grant access to nonlocal variables in enclosing subprograms. Recall that in Chapter 5, the problems introduced by this were discussed. For a long time, the only languages that allowed nested subprograms were those directly descending from ALGOL 60, which were ALGOL 68, Pascal, and Ada. Many other languages, including all of the direct descendants of C, do not allow subprogram nesting. Recently, some new languages again allow it. Among these are JavaScript, Python, and Ruby. Also, most functional programming languages allow subprograms to be nested.

9.5 Parameter-Passing Methods

Parameter-passing methods are the ways in which parameters are transmitted to and/or from called subprograms. First, we focus on the different semantics models of parameter-passing methods. Then, we discuss the various implementation models invented by language designers for these semantics models. Next, we survey the design choices of several languages and discuss the actual methods used to implement the implementation models. Finally, we consider the design considerations that face a language designer in choosing among the methods.

9.5.1 Semantics Models of Parameter Passing

Formal parameters are characterized by one of three distinct semantics models: (1) They can receive data from the corresponding actual parameter; (2) they can transmit data to the actual parameter; or (3) they can do both. These models are called **in mode**, **out mode**, and **inout mode**, respectively. For example, consider a subprogram that takes two arrays of `int` values as parameters—`list1` and `list2`. The subprogram must add `list1` to `list2` and return the result as a revised version of `list2`. Furthermore, the subprogram must create a new array from the two given arrays and return it. For this subprogram, `list1` should be in mode, because it is not to be changed by the subprogram. `list2` must be inout mode, because the subprogram needs the given value of the array and must return its new value. The third array should be out mode, because there is no initial value for this array and its computed value must be returned to the caller.

There are two conceptual models of how data transfers take place in parameter transmission: Either an actual value is copied (to the caller, to the called, or both ways) or an access path is transmitted. Most commonly, the access path is a simple pointer or reference. Figure 9.1 illustrates the three

semantics models of parameter passing when values are copied.

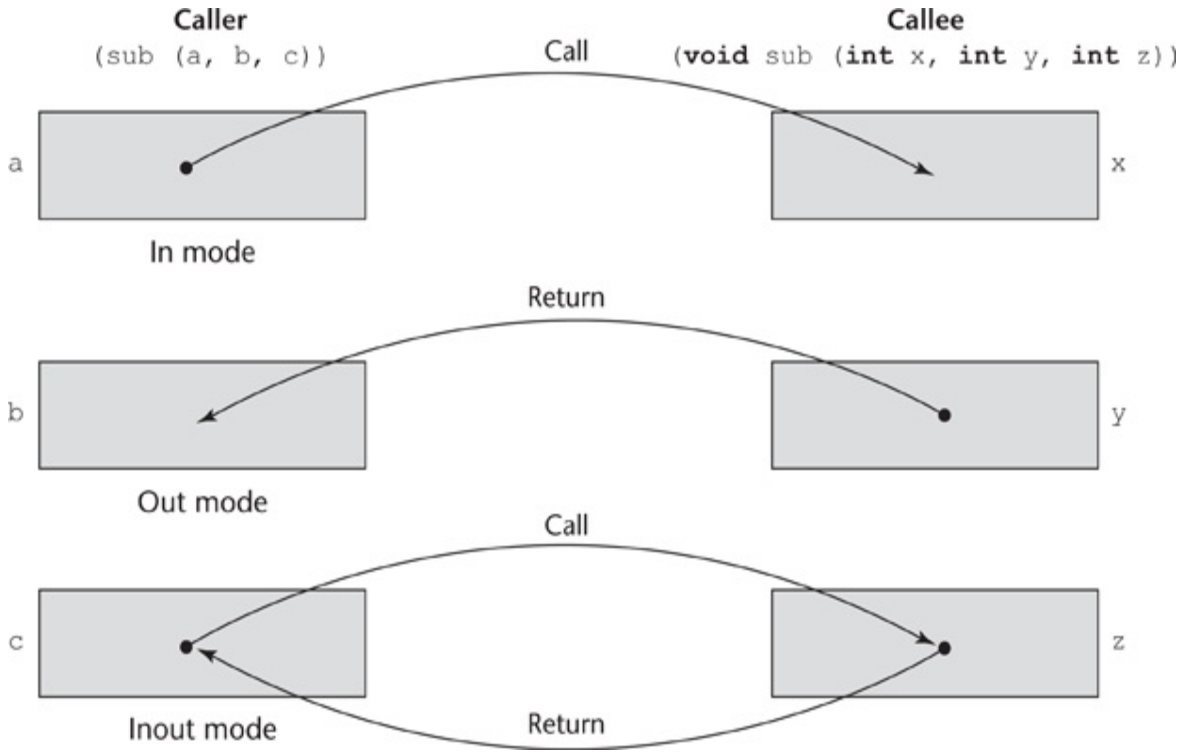


Figure 9.1 The three semantics models of parameter passing when physical moves are used

Figure 9.1 Full Alternative Text

9.5.2 Implementation Models of Parameter Passing

A variety of models have been developed by language designers to guide the implementation of the three basic parameter transmission modes. In the following sections, we discuss several of these, along with their relative

strengths and weaknesses.

9.5.2.1 Pass-by-Value

When a parameter is **passed by value**, the value of the actual parameter is used to initialize the corresponding formal parameter, which then acts as a local variable in the subprogram, thus implementing in-mode semantics.

Pass-by-value is normally implemented by copy, because accesses often are more efficient with this approach. It could be implemented by transmitting an access path to the value of the actual parameter in the caller, but that would require that the value be in a write-protected cell (one that can only be read). Enforcing the write protection is not always a simple matter. For example, suppose the subprogram to which the parameter was passed passes it in turn to another subprogram. This is another reason to use copy transfer. As we will see in Section 9.5.4, C++ provides a convenient and effective method for specifying write protection on pass-by-value parameters that are transmitted by access path.

The advantage of pass-by-value is that for scalars it is fast, in both linkage cost and access time.

The main disadvantage of the pass-by-value method if copies are used is that additional storage is required for the formal parameter, either in the called subprogram or in some area outside both the caller and the called subprogram. In addition, the actual parameter must be copied to the storage area for the corresponding formal parameter. The storage and the copy operations can be costly if the parameter is large, such as an array with many elements.

9.5.2.2 Pass-by-Result

Pass-by-result is an implementation model for out-mode parameters. When a parameter is passed by result, no value is transmitted to the subprogram. The corresponding formal parameter acts as a local variable, but just before

control is transferred back to the caller, its value is transmitted back to the caller's actual parameter, which obviously must be a variable. (How would the caller reference the computed result if it were a literal or an expression?)

The pass-by-result method has the advantages and disadvantages of pass-by-value, plus some additional disadvantages. If values are returned by copy (as opposed to access paths), as they typically are, pass-by-result also requires the extra storage and the copy operations that are required by pass-by-value. As with pass-by-value, the difficulty of implementing pass-by-result by transmitting an access path usually results in it being implemented by copy. In this case, the problem is in ensuring that the initial value of the actual parameter is not used in the called subprogram.

One additional problem with the pass-by-result model is that there can be an actual parameter collision, such as the one created with the call

```
sub(p1, p1)
```

In `sub`, assuming the two formal parameters have different names, the two can obviously be assigned different values. Then, whichever of the two is copied to their corresponding actual parameter last becomes the value of `p1` in the caller. Thus, the order in which the actual parameters are copied determines their value. For example, consider the following C# method, which specifies the pass-by-result method with the `out` specifier on its formal parameter.[5]

5. The **`out`** specifier must also be specified on the corresponding actual parameter.

```
void Fixer(out int x, out int y) {
  x = 17;
  y = 35;
}
. . .
f.Fixer(out a, out a);
```

If, at the end of the execution of `Fixer`, the formal parameter `x` is assigned to its corresponding actual parameter first, then the value of the actual parameter `a` in the caller will be `35`. If `y` is assigned first, then the value of the actual parameter `a` in the caller will be `17`.

Because the order can be implementation dependent for some languages, different implementations can produce different results.

Calling a subprogram with two identical actual parameters can also lead to different kinds of problems when other parameter-passing methods are used, as discussed in Section 9.5.2.4.

Another problem that can occur with pass-by-result is that the implementor may be able to choose between two different times to evaluate the addresses of the actual parameters: at the time of the call or at the time of the return. For example, consider the following C# method and following code:

```
void DoIt(out int x, int index){
  x = 17;
  index = 42;
}
. . .
sub = 21;
f.DoIt(list[sub], sub);
```

The address of `list[sub]` changes between the beginning and end of the method. The implementor must choose the time to bind this parameter to an address—at the time of the call or at the time of the return. If the address is computed on entry to the method, the value `17` will be returned to `list[21]`; if computed just before return, `17` will be returned to `list[42]`. This makes programs unportable between an implementation that chooses to evaluate the addresses for out-mode parameters at the beginning of a subprogram and one that chooses to do that evaluation at the end. An obvious way to avoid this problem is for the language designer to specify when the address to be used to return the parameter value must be computed.

9.5.2.3 Pass-by-Value-Result

Pass-by-value-result is an implementation model for inout-mode parameters in which actual values are copied. It is in effect a combination of pass-by-value and pass-by-result. The value of the actual parameter is used to initialize the corresponding formal parameter, which then acts as a local

variable. In fact, pass-by-value-result formal parameters must have local storage associated with the called subprogram. At subprogram termination, the value of the formal parameter is transmitted back to the actual parameter.

Pass-by-value-result is sometimes called **pass-by-copy**, because the actual parameter is copied to the formal parameter at subprogram entry and then copied back at subprogram termination.

Pass-by-value-result shares with pass-by-value and pass-by-result the - disadvantages of requiring multiple storage for parameters and time for copying values. It shares with pass-by-result the problems associated with the order in which actual parameters are assigned.

The advantages of pass-by-value-result are relative to pass-by-reference, so they are discussed in Section 9.5.2.4.

9.5.2.4 Pass-by-Reference

Pass-by-reference is a second implementation model for inout-mode parameters. Rather than copying data values back and forth, however, as in pass-by-value-result, the pass-by-reference method transmits an access path, usually just an address, to the called subprogram. This provides the access path to the cell storing the actual parameter. Thus, the called subprogram is allowed to access the actual parameter in the calling program unit. In effect, the actual parameter is shared with the called subprogram.

The advantage of pass-by-reference is that the passing process itself is efficient, in terms of both time and space. Duplicate space is not required and no copying is required.

There are, however, several disadvantages to the pass-by-reference method. First, access to the formal parameters will be slower than pass-by-value parameters, because of the additional level of indirect addressing that is required.6 Second, if only one-way communication to the called subprogram is required, inadvertent and erroneous changes may be made to the actual parameter. This issue is addressed below.

6. This is further explained in Section 9.5.3.

Another problem of pass-by-reference is that aliases can be created. This problem should be expected, because pass-by-reference makes access paths available to the called subprograms, thereby providing access to nonlocal variables. The problem with these kinds of aliasing is the same as in other circumstances: It is harmful to readability and thus to reliability. It also makes program verification more difficult. Another issue with pass by reference is whether the called subprogram is allowed to change a passed pointer. In C, this is possible, but in some other languages, such as Pascal and C++, formal parameters that are addresses are implicitly dereferenced in the called subprogram, which prevents such changes.

There are several ways pass-by-reference parameters can create aliases. First, collisions can occur between actual parameters. Consider a C++ function that has two parameters that are to be passed by reference, as in

```
void fun(int &first, int &second)
```

If the call to `fun` happens to pass the same variable twice, as in

```
fun(total, total)
```

then `first` and `second` in `fun` will be aliases.

Second, collisions between array elements can also cause aliases. For example, suppose the function `fun` is called with two array elements that are specified with variable subscripts, as in

```
fun(list[i], list[j])
```

If these two parameters are passed by reference and `i` happens to be equal to `j`, then `first` and `second` are again aliases.

Third, if two of the formal parameters of a subprogram are an element of an array and the whole array, and both are passed by reference, then a call such as

```
fun1(list[i], list)
```

could result in aliasing in `fun1`, because `fun1` can access all elements of `list` through the second parameter and access a single element through its first parameter.

Still another way to get aliasing with pass-by-reference parameters is through collisions between formal parameters and nonlocal variables that are visible. For example, consider the following C code:

```
int * global;
void main() {
   . . .
   sub(global);
   . . .
}
 void  sub(int  * param) {
   . . .
}
```

Inside `sub`, `param` and `global` are aliases.

All these possible aliasing situations are eliminated if pass-by-value-result is used instead of pass-by-reference. However, in place of aliasing, other problems sometimes arise, as discussed in Section 9.5.2.3.

9.5.2.5 Pass-by-Name

Pass-by-name is an inout-mode parameter transmission method that does not correspond to a single implementation model. When parameters are passed by name, the actual parameter is, in effect, textually substituted for the corresponding formal parameter in all its occurrences in the subprogram. This method is quite different from those discussed thus far; in which case, formal parameters are bound to actual values or addresses at the time of the subprogram call. A pass-by-name formal parameter is bound to an access method at the time of the subprogram call, but the actual binding to a value or an address is delayed until the formal parameter is assigned or referenced. Implementing a pass-by-name parameter requires a subprogram to be passed to the called subprogram to evaluate the address or value of the formal parameter. The referencing environment of the passed subprogram must also

be passed. This subprogram/referencing environment is a closure (see Section 9.12).7 Pass-by-name parameters are both complex to implement and inefficient. They also add significant complexity to the program, thereby lowering its readability and reliability.

7. These closures were originally (in ALGOL 60) called *thunks*.

Because pass-by-name is not part of any widely used language, it is not discussed further here. However, it is used at compile time by the macros in assembly languages and for the generic parameters of the generic subprograms in C++, Java 5.0, and C# 2005, as discussed in Section 9.9.

9.5.3 Implementing Parameter-Passing Methods

We now address the question of how the various implementation models of parameter passing are actually implemented.

In most contemporary languages, parameter communication takes place through the run-time stack. The run-time stack is initialized and maintained by the run-time system, which manages the execution of programs. The run-time stack is used extensively for subprogram control linkage and parameter passing, as discussed in Chapter 10. In the following discussion, we assume that the stack is used for all parameter transmission.

Pass-by-value parameters have their values copied into stack locations. The stack locations then serve as storage for the corresponding formal parameters. Pass-by-result parameters are implemented as the opposite of pass-by-value. The values assigned to the pass-by-result actual parameters are placed in the stack, where they can be retrieved by the calling program unit upon termination of the called subprogram. Pass-by-value-result parameters can be implemented directly from their semantics as a combination of pass-by-value and pass-by-result. The stack location for such a parameter is initialized by the call and is then used like a local variable in the called subprogram.

Pass-by-reference parameters are perhaps the simplest to implement. Most languages only allow variables to be passed by reference. However, Fortran passes all forms of parameters by reference. In Fortran, regardless of the type of the actual parameter, only its address must be placed in the stack. In the case of literals, the address of the literal is put in the stack. In the case of an expression, the compiler must build code to evaluate the expression, which must be executed just before the transfer of control to the called subprogram. The address of the memory cell in which the code places the result of its evaluation is then put in the stack. The Fortran compiler must prevent the called subprogram from changing parameters that are literals or expressions.

Access to the formal parameters in the called subprogram is by indirect addressing from the stack location of the address. The implementation of pass-by-value, -result, -value-result, and -reference, where the run-time stack is used, is shown in Figure 9.2. Subprogram `sub` is called from `main` with the call `sub(w, x, y, z)`, where `w` is passed by value, `x` is passed by result, `y` is passed by value-result, and `z` is passed by reference.

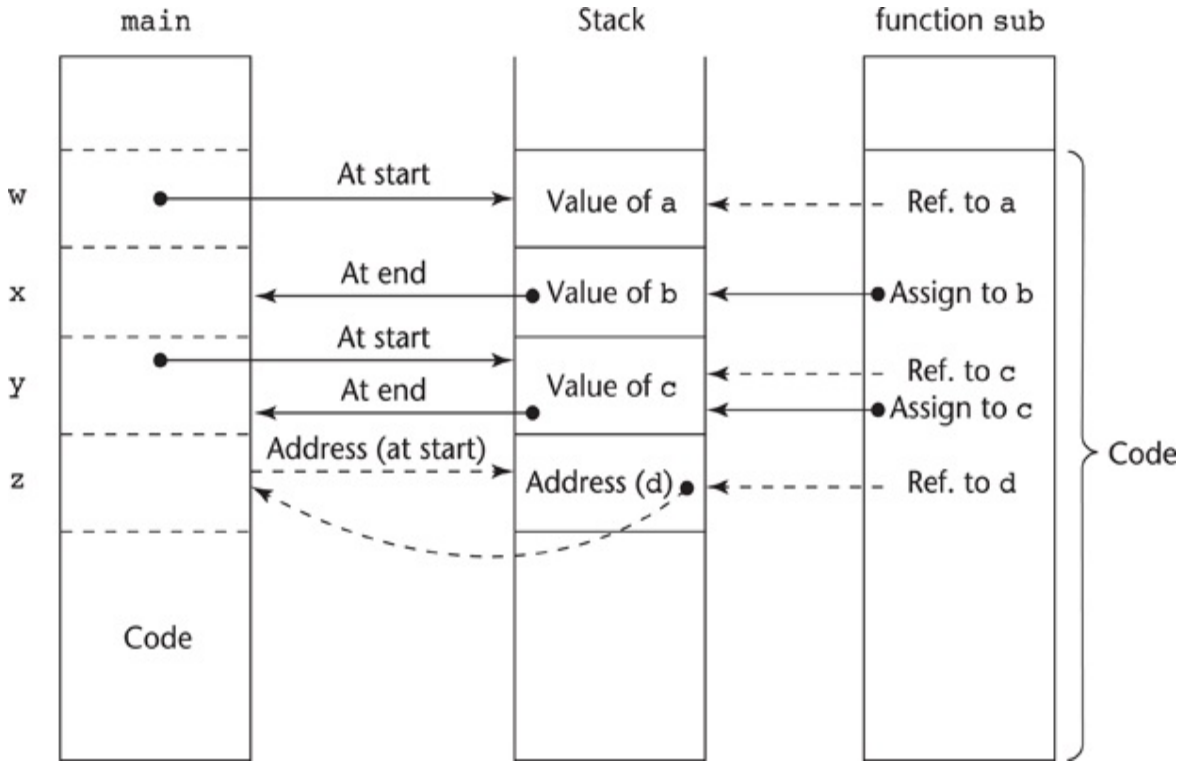

Figure 9.2 One possible stack

implementation of the common parameter-passing methods

Figure 9.2 Full Alternative Text

Function header: `void sub (int a, int b, int c, int d)`

Function call in `main`: `sub (w,x,y,z)`

(pass `w` by value, `x` by result, `y` by value-result, `z` by reference)

9.5.4 Parameter-Passing Methods of Some Common Languages

C uses pass-by-value. Pass-by-reference (inout mode) semantics is achieved by using pointers as parameters. The value of the pointer is made available to the called function and nothing is copied back. However, because what was passed is an access path to the data of the caller, the called function can change the caller's data. But all references to pointer formal parameter must be explicitly dereferenced in the function. C copied this use of the pass-by-value method from ALGOL 68. In both C and C++, formal parameters can be typed as pointers to constants. The corresponding actual parameters need not be constants, for in such cases they are coerced to constants. This allows pointer parameters to provide the efficiency of pass-by-reference with the one-way semantics of pass-by-value. Write protection of those parameters in the called function is implicitly specified.

C++ includes a special pointer type, called a *reference type*, as discussed in Chapter 6, which is often used for parameters. Reference parameters are implicitly dereferenced in the function or method, and their semantics is pass-by-reference. C++ also allows reference parameters to be defined to be constants. For example, we could have

```
void fun(const int &p1, int p2, int &p3) { . . . }
```

where `p1` is pass-by-reference but cannot be changed in the function `fun`, `p2` is pass-by-value, and `p3` is pass-by-reference. Neither `p1` nor `p3` need be explicitly dereferenced in `fun`.

history note

ALGOL 60 introduced the pass-by-name method. It also allowed pass-by-value as an option. Primarily because of the difficulty in implementing them, pass-by-name parameters were not carried from ALGOL 60 to any subsequent languages that became popular (other than SIMULA 67).

Constant parameters and in-mode parameters are not exactly alike. Constant parameters clearly implement in mode. However, in all of the common imperative languages except Ada, in-mode parameters can be assigned in the subprogram even though those changes are never reflected in the values of the corresponding actual parameters. In Ada, such an assignment is illegal. Constant parameters can never be assigned.

As with C and C++, all Java parameters are passed by value. However, because objects can be accessed only through reference variables, object parameters are in effect passed by reference. Although an object reference passed as a parameter cannot itself be changed in the called subprogram, the referenced object can be changed if a method is available to cause the change. Because reference variables cannot point to scalar variables directly and Java does not have pointers, scalars cannot be passed by reference in Java (although a reference to an object that contains a scalar can). Therefore, if a scalar is passed to a Java method, it cannot be changed by that method.

history note

ALGOL W (Wirth and Hoare, 1966) introduced the pass-by-value-result method of parameter passing as an alternative to the inefficiency of pass-by-name and the problems of pass-by-reference.

The default parameter-passing method of C# is pass-by-value. Pass-by-reference can be specified by preceding both a formal parameter and its corresponding actual parameter with **`ref`**. For example, consider the following C# skeletal method and call:

```
void sumer(ref int oldSum, int newOne) { . . . }
. . .
sumer(ref sum, newValue);
```

The first parameter to `sumer` is passed by reference; the second is passed by value. All **`ref`** parameters must be assigned a value before they are passed to an actual parameter.

C# also supports out-mode parameters, which are pass-by-reference parameters that do not need initial values. Such parameters are specified in the formal parameter list with the **`out`** modifier.

PHP's parameter passing is similar to that of C#, except that either the actual parameter or the formal parameter can specify pass-by-reference. Pass-by-reference is specified by preceding one or both of the parameters with an ampersand.

In Swift, the default parameter passing method is pass by value, and formal parameters passed this way cannot be changed in the called subprogram. Pass-by-reference semantics can be specified by preceding the formal parameter with the reserved word **`inout`**.

Perl employs a primitive means of passing parameters. All actual parameters are implicitly placed in a predefined array named `@_` (of all things!). The subprogram retrieves the actual parameter values (or addresses) from this array. The most peculiar thing about this array is its magical nature, exposed by the fact that its elements are in effect aliases for the actual parameters. Therefore, if an element of `@_` is changed in the called subprogram, that change is reflected in the corresponding actual parameter in the call, assuming there is a corresponding actual parameter (the number of actual parameters need not be the same as the number of formal parameters) and it is a variable.

The parameter-passing method of Python and Ruby is called **pass-by--**

assignment or **pass-by-sharing**. Because all data values are objects, every variable is a reference to an object. In pass-by-assignment, the actual parameter value is assigned to the formal parameter. Therefore, pass-by-assignment is in effect pass-by-reference, because the value of all actual parameters are references. However, only in certain cases does this result in pass-by-reference semantics. For example, many objects are essentially immutable. In a pure object-oriented language, the process of changing the value of a variable with an assignment statement, as in

```
x = x + 1
```

does not change the object referenced by `x`. Rather, it takes the object referenced by `x`, increments it by `1`, thereby creating a new object (with the value `x + 1`), and then changes `x` to reference the new object. So, when a reference to a scalar object is passed to a subprogram, the object being referenced cannot be changed in place. Because the reference is passed by value, even though the formal parameter is changed in the subprogram, that change has no effect on the actual parameter in the caller.

Now, suppose a reference to an array is passed as a parameter. If the corresponding formal parameter is assigned a new array object, there is no effect on the caller. However, if the formal parameter is used to assign a value to an element of the array, as in

```
list[3] = 47
```

the actual parameter is affected. So, changing the reference of the formal parameter has no effect on the caller, but changing an element of the array that is passed as a parameter does.

9.5.5 Type Checking Parameters

It is now widely accepted that software reliability demands that the types of actual parameters be checked for consistency with the types of the corresponding formal parameters. Without such type checking, small typographical errors can lead to program errors that may be difficult to diagnose because they are not detected by the compiler or the run-time

system. For example, in the function call

```
result = sub1(1)
```

the actual parameter is an integer constant. If the formal parameter of `sub1` is a floating-point type, no error will be detected without parameter type checking. Although an integer 1 and a floating-point 1 have the same value, the representations of these two are very different. `sub1` cannot produce a correct result given an integer actual parameter value if it expects a floating-point value.

Early programming languages, such as Fortran 77 and the original version of C, did not require parameter type checking; most later languages require it. However, the relatively recent languages Perl, JavaScript, and PHP do not.

C and C++ require some special discussion in the matter of parameter type checking. In the original C, neither the number of parameters nor their types were checked. In C89, the formal parameters of functions can be defined in two ways. They can be defined as in the original C; that is, the names of the parameters are listed in parentheses and the type declarations for them follow, as in the following function:

```
double sin(x)
  double x;
  { . . . }
```

Using this form avoids type checking, thereby allowing calls such as

```
double value;
int count;
. . .
value = sin(count);
```

to be legal, although they are never correct.

The alternative to the original C definition approach is called the **prototype** method, in which the formal parameter types are included in the list, as in

```
double sin(double x)
 { . . . }
```

If this version of `sin` is called with the same call, that is, with the following, it is also legal:

```
value = sin(count);
```

The type of the actual parameter (**`int`**) is checked against that of the formal parameter (**`double`**). Although they do not match, **`int`** is coercible to **`double`** (it is a widening coercion), so the conversion is done. If the conversion is not possible (for example, if the actual parameter had been an array) or if the number of parameters is wrong, then a semantics error is detected. So in C89, the user chooses whether parameters are to be type checked.

In C99 and C++, all functions must have their formal parameters in prototype form. However, type checking can be avoided for some of the parameters by replacing the last part of the parameter list with an ellipsis, as in

```
int  printf(const char* format_string, . . .);
```

A call to `printf` must include at least one parameter, a pointer to a literal character string. Beyond that, anything (including nothing) is legal. The way `printf` determines whether there are additional parameters is by the presence of format codes in the string parameter. For example, the format code for integer output is `%d`. This appears as part of the string, as in the following:

```
printf("The sum is %d\n", sum);
```

The `%` tells the `printf` function that there is one more parameter.

There is one more interesting issue with actual to formal parameter coercions when primitives can be passed by reference, as in C#. Suppose a call to a method passes a **`float`** value to a **`double`** formal parameter. If this parameter is passed by value, the **`float`** value is coerced to **`double`** and there is no problem. This particular coercion is very useful, for it allows a library to provide double versions of subprograms that can be used for both **`float`** and **`double`** values. However, suppose the parameter is passed by reference. When the value of the **`double`** formal parameter is returned to the **`float`** actual parameter in the caller, the value will overflow its location. To avoid this problem, C# requires the type of a **`ref`** actual parameter to match exactly the type of its corresponding formal parameter (no coercion is allowed).

In Python and Ruby, there is no type checking of parameters, because typing in these languages is a different concept. Objects have types, but variables do not, so formal parameters are typeless. This disallows the very idea of type checking parameters.

9.5.6 Multidimensional Arrays as Parameters

The storage-mapping functions that are used to map the index values of references to elements of multidimensional arrays to addresses in memory were discussed at length in Chapter 6. In some languages, such as C and C++, when a multidimensional array is passed as a parameter to a subprogram, the compiler must be able to build the mapping function for that array while seeing only the text of the subprogram (not the calling subprogram). This is true because the subprograms can be compiled separately from the programs that call them. Consider the problem of passing a matrix to a function in C. Multidimensional arrays in C are really arrays of arrays, and they are stored in row major order. Following is a storage-mapping function for row major order for matrices when the lower bound of all indices is 0 and the element size is 1:

- address `(mat[i, j]) =` address`(mat[0,0]) + i *`

  number_of_columns `+ j`

Notice that this mapping function needs the number of columns but not the number of rows. Therefore, in C and C++, when a matrix is passed as a parameter, the formal parameter must include the number of columns in the second pair of brackets. This is illustrated in the following skeletal C program:

```
void fun(int matrix[][10]) {
 . . . }
void main() {
  int mat[5][10];
  . . .
```

```
  fun(mat);
  . . .
}
```

The problem with this method of passing matrices as parameters is that it does not allow a programmer to write a function that can accept matrices with different numbers of columns; a new function must be written for every matrix with a different number of columns. This, in effect, disallows writing flexible functions that may be effectively reusable if the functions deal with multidimensional arrays. In C and C++, there is a way around the problem because of their inclusion of pointer arithmetic. The matrix can be passed as a pointer, and the actual dimensions of the matrix also can be passed as parameters. Then, the function can evaluate the user-written storage-mapping function using pointer arithmetic each time an element of the matrix must be referenced. For example, consider the following function prototype:

```
void fun(float *mat_ptr,
         int num_rows,
         int num_cols);
```

The following statement can be used to move the value of the variable `x` to the `[row][col]` element of the parameter matrix in `fun`:

```
*(mat_ptr + (row * num_cols) + col) = x;
```

Although this works, it is obviously difficult to read, and because of its complexity, it is error prone. The difficulty with reading this can be alleviated by using a macro to define the storage-mapping function, such as

```
#define mat_ptr(r,c) (*mat_ptr + ((r) *
                     (num_cols) + (c)))
```

With this, the assignment can be written as

```
mat_ptr(row,col) = x;
```

Other languages use different approaches to dealing with the problem of passing multidimensional arrays.

In Java and C#, arrays are objects. They are all single dimensioned, but the elements can be arrays. Each array inherits a named constant (`length` in Java

and `Length` in C#) that is set to the length of the array when the array object is created. The formal parameter for a matrix appears with two sets of empty brackets, as in the following Java method:

```
float sumer(float mat[][]) {
   float sum = 0.0f;
   for (int row = 0; row < mat.length; row++) {
     for (int col = 0; col < mat[row].length; col++) {
       sum += mat[row][col];
     }  //** for (int row . . .
   } //** for (int col . . .
   return sum;
}
```

Because each array has its own length value, in a matrix the rows can have different lengths.

9.5.7 Design Considerations

Two important considerations are involved in choosing parameter-passing methods: efficiency and whether one-way or two-way data transfer is needed.

Contemporary software-engineering principles dictate that access by subprogram code to data outside the subprogram should be minimized. With this goal in mind, in-mode parameters should be used whenever no data are to be returned through parameters to the caller. Out-mode parameters should be used when no data are transferred to the called subprogram but the subprogram must transmit data back to the caller. Finally, inout-mode parameters should be used only when data must move in both directions between the caller and the called subprogram.

There is a practical consideration that is in conflict with this principle. Sometimes it is justifiable to pass access paths for one-way parameter transmission. For example, when a large array is to be passed to a subprogram that does not modify it, a one-way method may be preferred. However, pass-by-value would require that the entire array be moved to a local storage area of the subprogram. This would be costly in both time and space. Because of this, large arrays are often passed by reference. This is

precisely the reason why the Ada 83 definition allowed implementors to choose between the two methods for structured parameters. C++ constant reference parameters offer another solution. Another alternative approach would be to allow the user to choose between the methods.

The choice of a parameter-passing method for functions is related to another design issue: functional side effects. This issue is discussed in Section 9.10.

9.5.8 Examples of Parameter Passing

Consider the following C function:

```
void swap1(int a, int b) {
  int temp = a;
  a = b;
  b = temp;
}
```

Suppose this function is called with

```
swap1(c, d);
```

Recall that C uses pass-by-value. The actions of `swap1` can be described by the following pseudocode:

```
a = c        - Move first parameter value in
b = d        - Move second parameter value in
temp = a
a = b
b = temp
```

Although `a` ends up with `d`'s value and `b` ends up with `c`'s value, the values of `c` and `d` are unchanged because nothing is transmitted back to the caller.

We can modify the C swap function to deal with pointer parameters to achieve the effect of pass-by-reference:

```
void swap2(int *a, int *b) {
  int temp = *a;
  *a = *b;
  *b = temp;
}
```

swap2 can be called with

```
swap2(&c, &d);
```

The actions of swap2 can be described with the following:

```
a = &c        - Move first parameter address in
b = &d        - Move second parameter address in
temp = *a
*a = *b
*b = temp
```

In this case, the swap operation is successful: The values of c and d are in fact interchanged. swap2 can be written in C++ using reference parameters as follows:

```
void swap2(int &a, int &b) {
   int  temp = a;
  a = b;
  b = temp;
}
```

This simple swap operation is not possible in Java, because it has neither pointers nor C++'s kind of references. In Java, a reference variable can point to only an object, not a scalar value.

The semantics of pass-by-value-result is identical to those of pass-by--reference, except when aliasing is involved. Ada uses pass-by-value-result for inout-mode scalar parameters. To explore pass-by-value-result, consider the following function, swap3, which we assume uses pass-by-value-result parameters. It is written in a syntax similar to that of Ada.

```
procedure swap3(a : in out Integer, b : in out Integer) is
  temp : Integer;
   begin
   temp := a;
   a := b;
```

```
   b := temp;
   end swap3
```

Suppose `swap3` is called with

```
swap3(c, d);
```

The actions of `swap3` with this call are

```
addr_c = &c         - Move first parameter address in
addr_d = &d         - Move second parameter address in
a = *addr_c         - Move first parameter value in
b = *addr_d         - Move second parameter value in
temp = a
a = b
b = temp
*addr_c = a         - Move first parameter value out
*addr_d = b         - Move second parameter value out
```

So once again, this swap subprogram operates correctly. Next, consider the call

```
swap3(i, list[i]);
```

In this case, the actions are

```
addr_i = &i           - Move first parameter address in
addr_listi= &list[i] - Move second parameter address in
a = *addr_i           - Move first parameter value in
b = *addr_listi       - Move second parameter value in
temp = a
a = b
b = temp
*addr_i = a           - Move first parameter value out
*addr_listi = b       - Move second parameter value out
```

Again, the subprogram operates correctly, in this case because the addresses to which to return the values of the parameters are computed at the time of the call rather than at the time of the return. If the addresses of the actual parameters were computed at the time of the return, the results would be wrong.

Finally, we must explore what happens when aliasing is involved with pass-

by-value-result and pass-by-reference. Consider the following skeletal program written in C-like syntax:

```
int i = 3; /* i is a global variable */
void fun(int a, int b) {
  i = b;
}
void main() {
  int list[10];
  list[i] = 5;
  fun(i, list[i]);
}
```

In `fun`, if pass-by-reference is used, `i` and `a` are aliases. If pass-by-value-result is used, `i` and `a` are not aliases. The actions of `fun`, assuming pass-by-value-result, are as follows:

```
addr_i = &i           - Move first parameter address in
addr_listi = &list[i] - Move second parameter address in
a = *addr_i           - Move first parameter value in
b = *addr_listi       - Move second parameter value in
i = b                 - Sets i to 5
*addr_i = a           - Move first parameter value out
*addr_listi = b       - Move second parameter value out
```

In this case, the assignment to the global `i` in `fun` changes its value from `3` to `5`, but the copy back of the first formal parameter (the second to last line in the example) sets it back to `3`. The important observation here is that if pass-by-reference is used, the result is that the copy back is not part of the semantics, and `i` remains `5`. Also note that because the address of the second parameter is computed at the beginning of `fun`, any change to the global `i` has no effect on the address used at the end to return the value of `list[i]`.

9.6 Parameters That Are Subprograms

In programming, a number of situations occur that are most conveniently handled if subprogram names can be sent as parameters to other subprograms. One common example of these occurs when a subprogram must sample some mathematical function. For example, a subprogram that does numerical integration estimates the area under the graph of a function by sampling the function at a number of different points. When such a subprogram is written, it should be usable for any given function; it should not need to be rewritten for every function that must be integrated. It is therefore natural that the name of a program function that evaluates the mathematical function to be integrated be sent to the integrating subprogram as a parameter.

Although the idea is natural and seemingly simple, the details of how it works can be confusing. If only the transmission of the subprogram code was necessary, it could be done by passing a single pointer. However, two complications arise.

First, there is the matter of type checking the parameters of the activations of the subprogram that was passed as a parameter. In C and C++, functions cannot be passed as parameters, but pointers to functions can. The type of a pointer to a function includes the function's protocol. Because the protocol includes all parameter types, such parameters can be completely type checked.

The second complication with parameters that are subprograms appears only with languages that allow nested subprograms. The issue is what referencing environment for executing the passed subprogram should be used. There are three choices:

- The environment of the call statement that enacts the passed subprogram (**shallow binding**)

- The environment of the definition of the passed subprogram (**deep binding**)

- The environment of the call statement that passed the subprogram as an actual parameter (**ad hoc binding**)

The following example program, written with the syntax of JavaScript, illustrates these choices:

```
function sub1() {
  var x;
  function sub2() {
    alert(x); // Creates a dialog box with the value of x
    };
  function  sub3() {
    var  x;
    x = 3;
    sub4(sub2);
    };
  function  sub4(subx) {
    var  x;
    x = 4;
    subx();
    };
  x = 1;
  sub3();
  };
```

Consider the execution of `sub2` when it is called in `sub4`. For shallow binding, the referencing environment of that execution is that of `sub4`, so the reference to `x` in `sub2` is bound to the local `x` in `sub4`, and the output of the program is `4`. For deep binding, the referencing environment of `sub2`'s execution is that of `sub1`, so the reference to `x` in `sub2` is bound to the local `x` in `sub1`, and the output is `1`. For ad hoc binding, the binding is to the local `x` in `sub3`, and the output is `3`.

In some cases, the subprogram that declares a subprogram also passes that subprogram as a parameter. In those cases, deep binding and ad hoc binding are the same. Ad hoc binding has never been used because, one might surmise, the environment in which the procedure appears as a parameter has no natural connection to the passed subprogram.

history note

The original definition of Pascal (Jensen and Wirth, 1974) allowed subprograms to be passed as parameters without including their parameter type information. If independent compilation is possible (it was not possible in the original Pascal), the compiler is not even allowed to check for the correct number of parameters. In the absence of independent compilation, checking for parameter consistency is possible but is a very complex task, and it usually is not done.

Shallow binding is not appropriate for static-scoped languages with nested subprograms. For example, suppose the procedure `Sender` passes the procedure `Sent` as a parameter to the procedure `Receiver`. The problem is that `Receiver` may not be in the static environment of `Sent`, thereby making it highly unnatural for `Sent` to have access to `Receiver`'s variables. On the other hand, it is perfectly normal in such a language for any subprogram, including one sent as a parameter, to have its referencing environment determined by the lexical position of its definition. It is therefore more logical for these languages to use deep binding. Some dynamic-scoped languages use shallow binding.

9.7 Calling Subprograms Indirectly

There are situations in which subprograms must be called indirectly. These most often occur when the specific subprogram to be called is not known until run time. The call to the subprogram is made through a pointer or reference to the subprogram, which has been set during execution before the call is made. The two most common applications of indirect subprogram calls are for event handling in graphical user interfaces, which are now part of nearly all Web applications, as well as many non-Web applications, and for callbacks, in which a subprogram is called and instructed to notify the caller when the called subprogram has completed its work. As always, our interest is not in these specific kinds of programming, but rather in programming language support for them.

The concept of calling subprograms indirectly is not a recently developed concept. C and C++ allow a program to define a pointer to a function, through which the function can be called. In C++, pointers to functions are typed according to the return type and parameter types of the function, so that such a pointer can point only at functions with one particular protocol. For example, the following declaration defines a pointer (`pfun`) that can point to any function that takes a **`float`** and an **`int`** as parameters and returns a **`float`**:

```
float (*pfun)(float,  int);
```

Any function with the same protocol as this pointer can be used as the initial value of this pointer or be assigned to the pointer in a program. In C and C++, a function name without following parentheses, like an array name without following brackets, is the address of the function (or array). So, both of the following are legal ways of giving an initial value or assigning a value to a pointer to a function:

```
int myfun2 (int, int);  // A function declaration
int (*pfun2)(int, int) = myfun2;  // Create a pointer and
                                  // initialize
                                  // it to point to myfun2
pfun2 = myfun2;  // Assigning a function's address to a
                 // pointer
```

The function `myfun2` can now be called with either of the following statements:

```
(*pfun2)(first, second); pfun2(first, second);
```

The first of these explicitly dereferences the pointer `pfun2`, which is legal, but unnecessary.

The function pointers of C and C++ can be sent as parameters and returned from functions, although functions cannot be used directly in either of those roles.

In C#, the power and flexibility of method pointers is increased by making them objects. These are called **delegates**, because instead of calling a method, a program delegates that action to a delegate.

To use a delegate, first the delegate class must be defined with a specific method protocol. An instantiation of a delegate holds the name of a method with the delegate's protocol that it is able to call. The syntax of a declaration of a delegate is the same as that of a method declaration, except that the reserved word **`delegate`** is inserted just before the return type. For example, we could have the following:

```
public delegate int Change(int x);
```

This delegate can be instantiated with any method that takes an **`int`** as a parameter and returns an **`int`**. For example, consider the following method declaration:

```
static int fun1(int x);
```

The delegate `Change` can be instantiated by sending the name of this method to the delegate's constructor, as in the following:

```
Change chgfun1 =  new  Change(fun1);
```

This can be shortened to the following:

```
Change chgfun1 = fun1;
```

Following is an example call to `fun1` through the delegate `chgfun1`:

```
chgfun1(12);
```

Objects of a delegate class can store more than one method. A second method can be added using the operator `+=`, as in the following:

```
Change chgfun1 += fun2;
```

This places `fun2` in the `chgfun1` delegate, even if `chgfun1` previously had the value **`null`**. All of the methods stored in a delegate instance are called in the order in which they were placed in the instance. This is called a **multicast delegate**. Regardless of what is returned by the methods, only the value or object returned by the last one called is returned. Of course, this means that in most cases, **`void`** is returned by the methods called through a multicast delegate.

In our example, a static method is placed in the delegate `Change`. Instance methods can also be called through a delegate, in which case the delegate must store a reference to the method. Delegates can also be generic.

Delegates are used for event handling by .NET applications. They are also used to implement closures (see Section 9.12).

As is the case with C and C++, the name of a function in Python without the following parentheses is a pointer to that function. Ada 95 has pointers to subprograms, but Java does not. In Python and Ruby, as well as most functional languages, subprograms are treated like data, so they can be assigned to variables. Therefore, in these languages, there is little need for pointers to subprograms.

9.8 Design Issues for Functions

The following design issues are specific to functions:

- Are side effects allowed?
- What types of values can be returned?
- How many values can be returned?

9.8.1 Functional Side Effects

Because of the problems of side effects of functions that are called in expressions, as described in Chapter 5, parameters to functions should always be in-mode. In fact, some languages require this; for example, Ada functions can have only in-mode formal parameters. This requirement effectively prevents a function from causing side effects through its parameters or through aliasing of parameters and globals. In most other imperative languages, however, functions can have either pass-by-value or pass-by-reference parameters, thus allowing functions that cause side effects and aliasing.

Pure functional languages, such as Haskell and Ruby, do not have variables, so their functions cannot have side effects.

9.8.2 Types of Returned Values

Most imperative programming languages restrict the types that can be returned by their functions. C allows any type to be returned by its functions except arrays and functions. Both of these can be handled by pointer type return values. C++ is like C but also allows user-defined types, or classes, to be returned from its functions. Ada, Python, and Ruby are the only languages

among current imperative languages whose functions (and/or methods) can return values of any type. In the case of Ada, however, because functions are not types in Ada, they cannot be returned from functions. Of course, pointers to functions can be returned by functions.

In some programming languages, subprograms are first-class objects, which means that they can be passed as parameters, returned from functions, and assigned to variables. Methods are first-class objects in some imperative languages, for example, Python and Ruby. The same is true for the functions in most functional languages.

Neither Java nor C# can have functions, although their methods are similar to functions. In both, any type or class can be returned by methods. Because methods are not types, they cannot be returned.

9.8.3 Number of Returned Values

In most languages, only a single value can be returned from a function. However, that is not always the case. Ruby allows the return of more than one value from a method. If a `return` statement in a Ruby method is not followed by an expression, `nil` is returned. If followed by one expression, the value of the expression is returned. If followed by more than one expression, an array of the values of all of the expressions is returned.

In ML, F#, and Python, and some other languages that include tuples, multiple values can be returned by placing them in a tuple.

9.9 Overloaded Subprograms

An overloaded operator is one that has multiple meanings. The meaning of a particular instance of an overloaded operator is determined by the types of its operands. For example, if the * operator has two floating-point operands in a Java program, it specifies floating-point multiplication. But if the same operator has two integer operands, it specifies integer multiplication.

An **overloaded subprogram** is a subprogram that has the same name as another subprogram in the same referencing environment. Every version of an overloaded subprogram must have a unique protocol; that is, it must be different from the others in the number, order, or types of its parameters, and possibly in its return type. The meaning of a call to an overloaded subprogram is determined by the actual parameter list and/or possibly the type of the returned value. Although it is not necessary, overloaded subprograms usually implement the same process.

C++, Java, and C# include predefined overloaded subprograms. For example, many classes in C++, Java, and C# have overloaded constructors. Because each version of an overloaded subprogram has a unique parameter profile, the compiler can disambiguate occurrences of calls to them by the different type parameters. Unfortunately, it is not that simple. Parameter coercions, when allowed, complicate the disambiguation process enormously. Simply stated, the issue is that if no method's parameter profile matches the number and types of the actual parameters in a method call, but two or more methods have parameter profiles that can be matched through coercions, which method should be called? For a language designer to answer this question, he or she must decide how to rank all of the different coercions, so that the compiler can choose the method that "best" matches the call. This can be a complicated task. To understand the level of complexity of this process, we suggest the reader refer to the rules for disambiguation of method calls used in C++ (Stroustrup, 1997).

Because C++, Java, and C# allow mixed-mode expressions, the return type is irrelevant to disambiguation of overloaded functions (or methods). The

context of the call does not allow the determination of the return type. For example, if a C++ program has two functions named `fun` and both take an `int` parameter but one returns an `int` and one returns a `float`, the program would not compile, because the compiler could not determine which version of `fun` should be used.

Users are also allowed to write multiple versions of subprograms with the same name in Java, C++, C#, and F#. Once again, in C++, Java, and C# the most common user-defined overloaded methods are constructors.

Overloaded subprograms that have default parameters can lead to ambiguous subprogram calls. For example, consider the following C++ code:

```
void fun(float b = 0.0);
void fun();
  . . .
  fun();
```

The call is ambiguous and will cause a compilation error.

9.10 Generic Subprograms

Software reuse can be an important contributor to software productivity. One way to increase the reusability of software is to lessen the need to create different subprograms that implement the same algorithm on different types of data. For example, a programmer should not need to write four different sort subprograms to sort four arrays that differ only in element type.

A **polymorphic** subprogram takes parameters of different types on different activations. Overloaded subprograms provide a particular kind of polymorphism called **ad hoc polymorphism**. Overloaded subprograms need not behave similarly.

Languages that support object-oriented programming usually support subtype polymorphism. **Subtype polymorphism** means that a variable of type T can access any object of type T or any type derived from T.

A more general kind of polymorphism is provided by the methods of Python and Ruby. Recall that variables in these languages do not have types, so formal parameters do not have types. Therefore, a method will work for any type of actual parameter, as long as the operators used on the formal parameters in the method are defined.

Parametric polymorphism is provided by a subprogram that takes generic parameters that are used in type expressions that describe the types of the parameters of the subprogram. Different instantiations of such subprograms can be given different generic parameters, producing subprograms that take different types of parameters. Parametric definitions of subprograms all behave the same. Parametrically polymorphic subprograms are often called **generic** subprograms. C++, Java 5.0+, C# 2005+, and F# provide a kind of compile-time parametric polymorphism.

9.10.1 Generic Functions in C++

Generic functions in C++ have the descriptive name of *template functions*. The definition of a template function has the general form

- **`template`** <template parameters>

—a function definition that may include the template parameters

A template parameter (there must be at least one) has one of the forms

- **`class`** identifier
- **`typename`** identifier

The class form is used for type names. The `typename` form is used for passing a value to the template function. For example, it is sometimes convenient to pass an integer value for the size of an array in the template function.

A template can take another template, in practice often a template class that defines a user-defined generic type, as a parameter, but we do not consider that option here.8

8. Template classes are discussed in Chapter 11.

As an example of a template function, consider the following:

```
template <class Type>
Type max(Type first, Type second) {
  return  first > second ? first : second;
}
```

where `Type` is the parameter that specifies the type of data on which the function will operate. This template function can be instantiated for any type for which the operator `>` is defined. For example, if it were instantiated with **`int`** as the parameter, it would be

```
int max(int  first, int second) {
  return first > second ? first : second;
}
```

Although this process could be defined as a macro, a macro would have the

disadvantage of not operating correctly if the parameters were expressions with side effects. For example, suppose the macro were defined as

```
#define max(a, b) ((a) > (b)) ? (a) : (b)
```

This definition is generic in the sense that it works for any numeric type. However, it does not always work correctly if called with a parameter that has a side effect, such as

```
max(x++, y)
```

which produces

```
((x++) > (y) ? (x++) : (y))
```

Whenever the value of `x` is greater than that of `y`, `x` will be incremented twice.

C++ template functions are instantiated implicitly either when the function is named in a call or when its address is taken with the `&` operator. For example, the example template function `max` would be instantiated twice by the following code segment—once for **`int`** type parameters and once for **`char`** type parameters:

```
int a, b, c;
char d, e, f;
. . .
c = max(a, b);
f = max(d, e);
```

The following is a C++ generic sort subprogram:

```
template <class Type>
void generic_sort(Type list[], int len) {
  int top, bottom;
  Type temp;
  for (top = 0; top < len - 2; top++)
    for (bottom = top + 1; bottom < len - 1; bottom++)
      if (list[top] > list[bottom]) {
        temp = list[top];
        list[top] = list[bottom];
        list[bottom] = temp;
      }  //** end of if (list[top] . . .
}  //** end of generic_sort
```

The following is an example instantiation of this template function:

```
float flt_list[100];
. . .
generic_sort(flt_list, 100);
```

The templated functions of C++ are a kind of poor cousin to a subprogram in which the types of the formal parameters are dynamically bound to the types of the actual parameters in a call. In this case, only a single copy of the code is needed, whereas with the C++ approach, a copy must be created at compile time for each different type that is required and the binding of subprogram calls to subprograms is static.

9.10.2 Generic Methods in Java 5.0

Support for generic types and methods was added to Java in Java 5.0. The name of a generic class in Java 5.0 is specified by a name followed by one or more type variables delimited by pointed brackets. For example,

```
generic_class<T>
```

where `T` is the type variable. Generic types are discussed in more detail in Chapter 11.

Java's generic methods differ from the generic subprograms of C++ in several important ways. First, generic parameters must be classes—they cannot be primitive types. This requirement disallows a generic method that mimics our example in C++, in which the component types of arrays are generic and can be primitives. In Java, the components of arrays (as opposed to containers) cannot be generic. Second, although Java generic methods can be instantiated any number of times, only one copy of the code is built. The internal version of a generic method, which is called a *raw* method, operates on `Object` class objects. At the point where the generic value of a generic method is returned, the compiler inserts a cast to the proper type. Third, in Java, restrictions can be specified on the range of classes that can be passed

to the generic method as generic parameters. Such restrictions are called **bounds**.

As an example of a generic Java 5.0 method, consider the following skeletal method definition:

```
public static  <T> T doIt(T[] list) {
  . . .
}
```

This defines a method named `doIt` that takes an array of elements of a generic type. The name of the generic type is `T` and it must be an array. Following is an example call to `doIt`:

```
doIt<string>(myList);
```

Now, consider the following version of `doIt`, which has a bound on its generic parameter:

```
public static <T extends Comparable> T doIt(T[] list) {
  . . .
}
```

This defines a method that takes a generic array parameter whose elements are of a class that implements the `Comparable` interface. That is the restriction, or bound, on the generic parameter. The reserved word **`extends`** seems to imply that the generic class subclasses the following class. In this context, however, **`extends`** has a different meaning. The expression `<T extends BoundingType>` specifies that `T` should be a "subtype" of the bounding type. So, in this context, **`extends`** means the generic class (or interface) either extends the bounding class (the bound if it is a class) or implements the bounding interface (if the bound is an interface). The bound ensures that the elements of any instantiation of the generic can be compared with the `Comparable` method, `compareTo`.

If a generic method has two or more restrictions on its generic type, they are added to the **`extends`** clause, separated by ampersands (`&`). Also, generic methods can have more than one generic parameter.

Java 5.0 supports *wildcard types*. For example, `Collection<?>` is a wildcard

type for collection classes. This type can be used for any collection type of any class components. For example, consider the following generic method:

```
void  printCollection(Collection<?> c) {
   for  (Object e: c) {
     System.out.println(e);
  }
}
```

This method prints the elements of any `Collection` class, regardless of the class of its components. Some care must be taken with objects of the wildcard type. For example, because the components of a particular object of this type have a type, other type objects cannot be added to the collection. For example, consider

```
Collection<?> c = new ArrayList<String>();
```

It would be illegal to use the `add` method to put something into this collection unless its type were `String`.

Wildcard types can be restricted, as is the case with nonwildcard types. Such types are called *bounded wildcard types*. For example, consider the following method header:

```
public void drawAll(ArrayList<? extends Shape> things)
```

The generic type here is a wildcard type that is a subclass of the `Shape` class. This method could be written to draw any object whose type is a subclass of `Shape`.

9.10.3 Generic Methods in C# 2005

The generic methods of C# 2005 are similar in capability to those of Java 5.0, except there is no support for wildcard types. One unique feature of C# 2005 generic methods is that the actual type parameters in a call can be omitted if the compiler can infer the unspecified type. For example, consider the

following skeletal class definition:

```
class MyClass {
  public static  T DoIt<T>(T p1) {
    . . .
  }
}
```

The method `DoIt` can be called without specifying the generic parameter if the compiler can infer the generic type from the actual parameter in the call. For example, both of the following calls are legal:

```
int myInt = MyClass.DoIt(17);  // Calls DoIt<int>
string myStr = MyClass.DoIt('apples');
    // Calls DoIt<string>
```

9.10.4 Generic Functions in F#

The type inferencing system of F# is not always able to determine the type of parameters or the return type of a function. When this is the case, for some functions F# infers a generic type for the parameters and the return value. This is called **automatic generalization**. For example, consider the following function definition:

```
let getLast (a, b, c) = c;;
```

Because no type information was included, the types of the parameters and the return value are all inferred to be generic. Because this function does not include any computations, this is a simple generic function.

Functions can be defined to have generic parameters, as in the following example:

```
let printPair (x: 'a) (y: 'a) =
   printfn "%A %A" x y;;
```

The `%A` format specification is for any type. The apostrophe in front of the type named a specifies it to be a generic type.[9] This function definition works (with generic parameters) because no type-constrained operation is included.

Arithmetic operators are examples of type-constrained operations. For example, consider the following function definition:

9. There is nothing special about a—it could be any legal identifier. By convention, lowercase letters at the beginning of the alphabet are used.

```
let adder x y = x + y;;
```

Type inferencing sets the type of `x` and `y` and the return value to **`int`**. Because there is no type coercion in F#, the following call is illegal:

```
adder 2.5 3.6;;
```

Even if the type of the parameters were set to be generic, the `+` operator would cause the types of `x` and `y` to be **`int`**.

The generic type could also be specified explicitly in angle brackets, as in the following:

```
let printPair2<'T> x y =
    printfn "%A %A" x y;;
```

This function must be called with a type,10 as in the following:

10. Convention explicitly states that generic types are named with uppercase letters starting at T.

```
printPair2<float> 3.5 2.4;;
```

Because of type inferencing and the lack of type coercions, F# generic functions are far less useful, especially for numeric computations, than those of C+ +, Java 5.0+, and C# 2005+.

9.11 User-Defined Overloaded Operators

Operators can be overloaded by the user in Ada, C++, Python, and Ruby. Suppose that a Python class is developed to support complex numbers and arithmetic operations on them. A complex number can be represented with two floating-point values. The `Complex` class would have members for these two named `real` and `imag`. In Python, binary arithmetic operations are implemented as method calls sent to the first operand, sending the second operand as a parameter. For addition, the method is named `__add__`. For example, the expression `x + y` is implemented as `x.__add__(y)`. To overload `+` for the addition of objects of the new `Complex` class, we only need to provide `Complex` with a method named `__add__` that performs the operation. Following is such a method:

```
def __add__ (self, second):
  return Complex(self.real + second.real, self.imag +
   second.imag)
```

In most languages that support object-oriented programming, a reference to the current object is implicitly sent with each method call. In Python, this reference must be sent explicitly; that is the reason why `self` is the first parameter to our method, `__add__`.

The example add method could be written for a complex class in C++ as follows11 :

11. Both C++ and Python have predefined classes for complex numbers, so our example methods are unnecessary, except as illustrations.

```
Complex operator +(Complex &second) {
  return  Complex(real + second.real, imag + second.imag);
}
```

9.12 Closures

Defining a closure is a simple matter; a **closure** is a subprogram and the referencing environment where it was defined. The referencing environment is needed if the subprogram can be called from any arbitrary place in the program. Explaining a closure is not so simple.

If a static-scoped programming language does not allow nested subprograms, closures are not useful, so such languages do not support them. All of the variables in the referencing environment of a subprogram in such a language (its local variables and the global variables) are accessible, regardless of the place in the program where the subprogram is called.

When subprograms can be nested, in addition to locals and globals, the referencing environment of a subprogram can include variables defined in all enclosing subprograms. However, this is not an issue if the subprogram can be called only in places where all of the enclosing scopes are active and visible. It becomes an issue if a subprogram can be called elsewhere. This can happen if the subprogram can be passed as a parameter or assigned to a variable, thereby allowing it to be called from virtually anywhere in the program. There is an associated problem: The subprogram could be called after one or more of its nesting subprograms has terminated, which normally means that the variables defined in such nesting subprograms have been deallocated—they no longer exist. For the subprogram to be callable from anywhere in the program, its referencing environment must be available wherever it might be called. Therefore, the variables defined in nesting subprograms may need lifetimes that are of the entire program, rather than just the time during which the subprogram in which they were defined is active. A variable whose lifetime is that of the whole program is said to have **unlimited extent**. This usually means they must be heap dynamic, rather than stack dynamic.

Nearly all functional programming languages, most scripting languages, and at least one primarily imperative language, C#, support closures. These languages are static-scoped, allow nested subprograms,[12] and allow

subprograms to be passed as parameters. Following is an example of a closure written in JavaScript:

12. In C#, the only methods that can be nested are anonymous delegates and lambda expressions.

```
function makeAdder(x) {
    return function(y) {return x + y;}
}
. . .
var add10 = makeAdder(10);
var add5 = makeAdder(5);
document.write("Add 10 to 20: " + add10(20) +
"<br />");
document.write("Add 5 to 20: " + add5(20) +
"<br />");
```

The output of this code, assuming it was embedded in an HTML document and displayed with a browser, is as follows:

```
Add 10 to 20: 30
Add 5 to 20: 25
```

In this example, the closure is the anonymous function defined inside the `makeAdder` function, which `makeAdder` returns. The variable `x` referenced in the closure function is bound to the parameter that was sent to `makeAdder`. The `makeAdder` function is called twice, once with a parameter of `10` and once with `5`. Each of these calls returns a different version of the closure because they are bound to different values of `x`. The first call to `makeAdder` creates a function that adds `10` to its parameter; the second creates a function that adds `5` to its parameter. The two versions of the function are bound to different activations of `makeAdder`. Obviously, the lifetime of the version of `x` created when `makeAdder` is called must extend over the lifetime of the program.

This same closure function can be written in C# using a nested anonymous delegate. The type of the nesting method is specified to be a function that takes an **`int`** as a parameter and returns an anonymous delegate. The return type is specified with the special notation for such delegates, `Func<int, int>`. The first type in the angle brackets is the parameter type. Such a delegate can encapsulate methods that have only one parameter. The second

type is the return type of the method encapsulated by the delegate.

```
static Func<int, int> makeAdder(int x) {
  return delegate(int y) { return x + y;};
}
. . .
Func<int, int> Add10 = makeAdder(10);
Func<int, int> Add5 = makeAdder(5);
Console.WriteLine("Add 10 to 20: {0}", Add10(20));
Console.WriteLine("Add 5 to 20: {0}", Add5(20));
```

The output of this code is exactly the same as for the previous JavaScript closure example.

The anonymous delegate could have been written as a lambda expression. The following is a replacement for the body of the `makeAdder` method, using a lambda expression instead of the delegate:

```
return y => x + y
```

Ruby’s blocks are implemented so that they can reference variables visible in the position in which they were defined, even if they are called at a place in which those variables would have disappeared. This makes such blocks closures.

9.13 Coroutines

A **coroutine** is a special kind of subprogram. Rather than the master-slave relationship between a caller and a called subprogram that exists with conventional subprograms, caller and called coroutines are more equitable. In fact, the coroutine control mechanism is often called the **symmetric unit control model**.

Coroutines can have multiple entry points, which are controlled by the coroutines themselves. They also have the means to maintain their status between activations. This means that coroutines must be history sensitive and thus have static local variables. Secondary executions of a coroutine often begin at points other than its beginning. Because of this, the invocation of a coroutine is called a **resume** rather than a call.

For example, consider the following skeletal coroutine:

```
sub co1(){
  . . .
  resume  co2();
  . . .
  resume  co3();
  . . .
}
```

The first time `co1` is resumed, its execution begins at the first statement and executes down to and including the resume of `co2`, which transfers control to `co2`. The next time `co1` is resumed, its execution begins at the first statement after its call to `co2`. When `co1` is resumed the third time, its execution begins at the first statement after the resume of `co3`.

One of the usual characteristics of subprograms is maintained in coroutines: Only one coroutine is actually in execution at a given time.

As seen in the example above, rather than executing to its end, a coroutine often partially executes and then transfers control to some other coroutine, and when restarted, a coroutine resumes execution just after the statement it

used to transfer control elsewhere. This sort of interleaved execution sequence is related to the way multiprogramming operating systems work. Although there may be only one processor, all of the executing programs in such a system appear to run concurrently while sharing the processor. In the case of coroutines, this is sometimes called **quasi-concurrency**.

Typically, coroutines are created in an application by a program unit called the master unit, which is not a coroutine. When created, coroutines execute their initialization code and then return control to that master unit. When the entire family of coroutines is constructed, the master program resumes one of the coroutines, and the members of the family of coroutines then resume each other in some order until their work is completed, if in fact it can be completed. If the execution of a coroutine reaches the end of its code section, control is transferred to the master unit that created it. This is the mechanism for ending execution of the collection of coroutines, when that is desirable. In some programs, the coroutines run whenever the computer is running.

One example of a problem that can be solved with this sort of collection of coroutines is a card game simulation. Suppose the game has four players who all use the same strategy. Such a game can be simulated by having a master program unit create a family of four coroutines, each with a collection, or hand, of cards. The master program could then start the simulation by resuming one of the player coroutines, which, after it had played its turn, could resume the next player coroutine, and so forth until the game ended.

Suppose program units `A` and `B` are coroutines. Figure 9.3 shows two ways an execution sequence involving `A` and `B` might proceed.

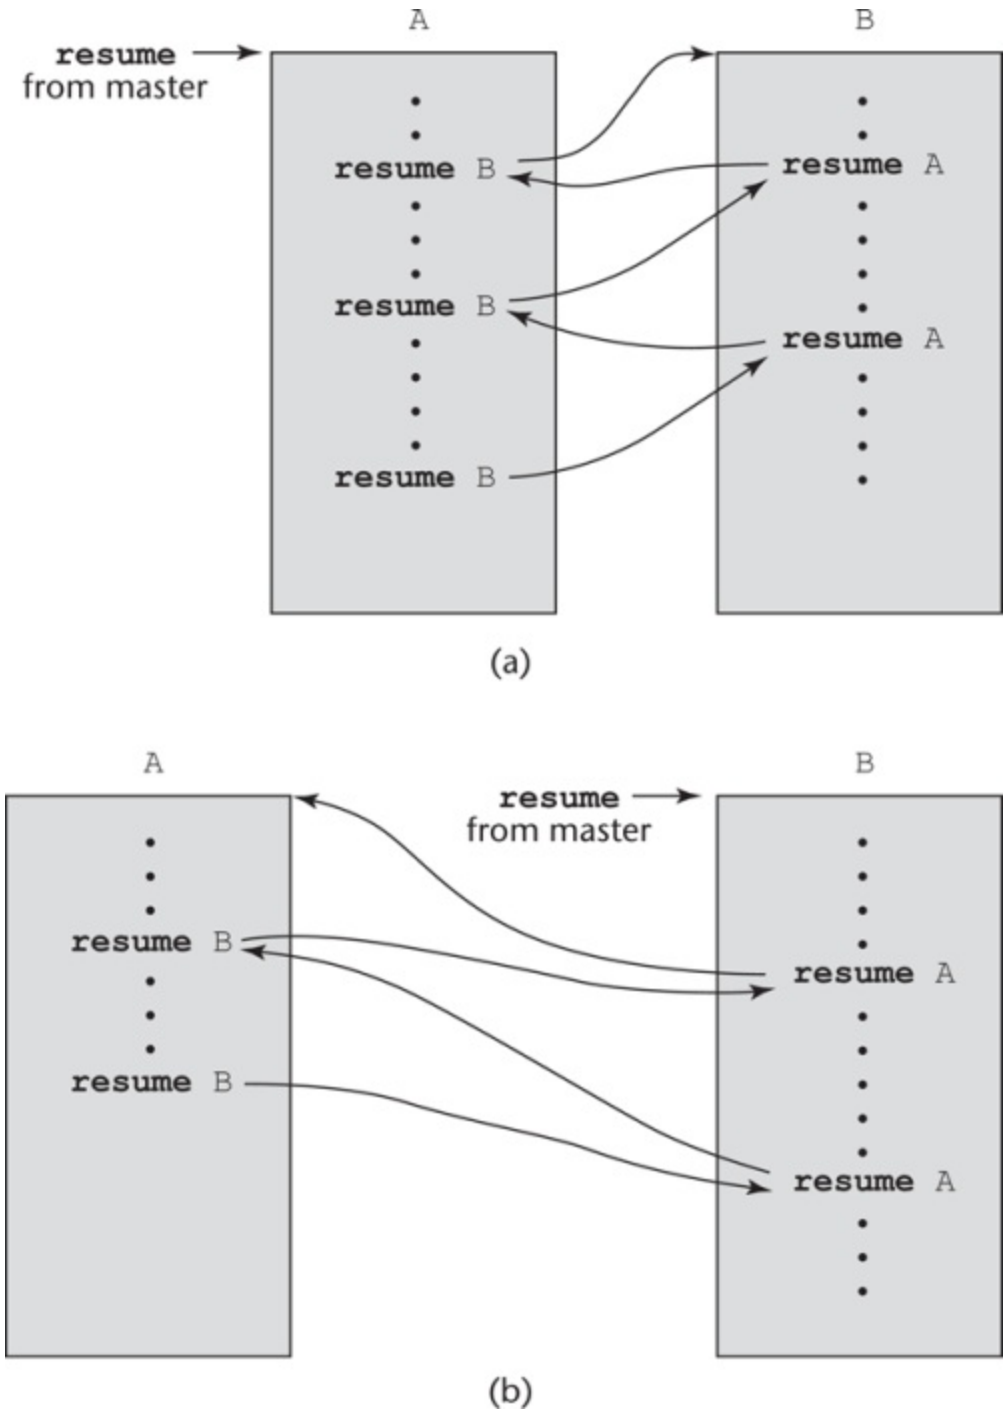

Figure 9.3 Two possible execution control sequences for

two coroutines without loops

Figure 9.3 Full Alternative Text

In Figure 9.3a, the execution of coroutine A is started by the master unit. After some execution, A starts B. When coroutine B in Figure 9.3a first causes control to return to coroutine A, the semantics is that A continues from where it ended its last execution. In particular, its local variables have the values left them by the previous activation. Figure 9.3b shows an alternative execution sequence of coroutines A and B. In this case, B is started by the master unit.

Rather than have the patterns shown in Figure 9.3, a coroutine often has a loop containing a resume. Figure 9.4 shows the execution sequence of this scenario. In this case, A is started by the master unit. Inside its main loop, A resumes B, which in turn resumes A in its main loop.

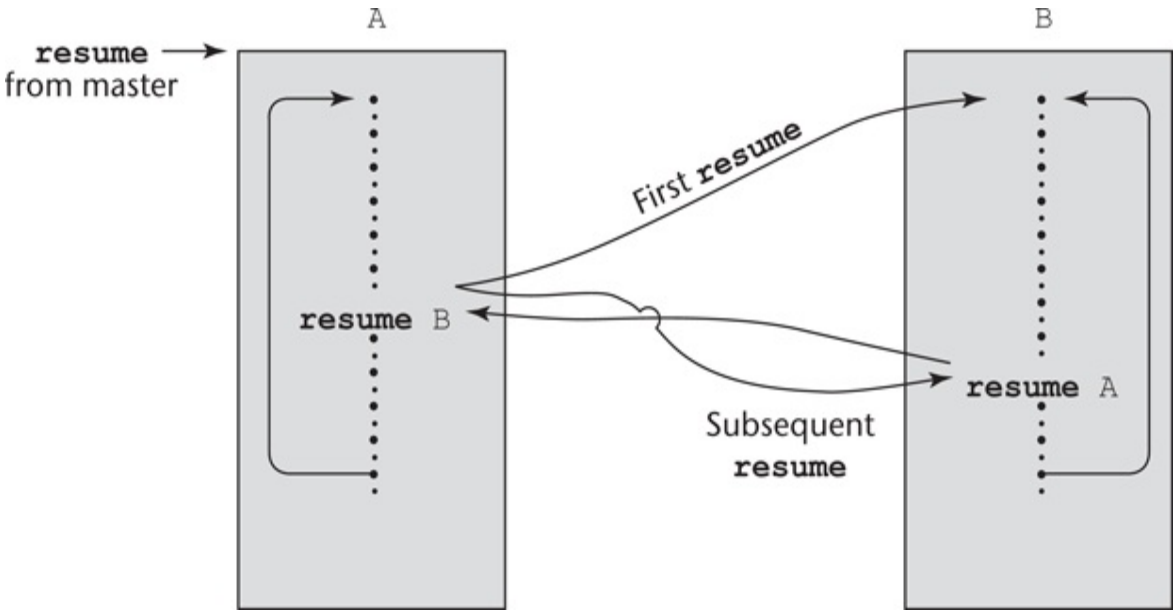

Figure 9.4 Coroutine execution sequence with loops

Figure 9.4 Full Alternative Text

The generators of Python are a form of coroutines.13

13. However, the generators of Python are a form of coroutines.

SUMMARY

Process abstractions are represented in programming languages by subprograms. A subprogram definition describes the actions represented by the subprogram. A subprogram call enacts those actions. A subprogram header identifies a subprogram definition and provides its interface, which is called its protocol.

Formal parameters are the names that subprograms use to refer to the actual parameters given in subprogram calls. In Python and Ruby, array and hash formal parameters are used to support variable numbers of parameters. JavaScript also supports variable numbers of parameters. Actual parameters can be associated with formal parameters by position or by keyword. Parameters can have default values.

Subprograms can be either functions, which model mathematical functions and are used to define new operations, or procedures, which define new statements.

Local variables in subprograms can be stack dynamic, providing support for recursion, or static, providing efficiency and history-sensitive local variables.

JavaScript, Python, Ruby, and Swift allow subprogram definitions to be nested.

There are three fundamental semantics models of parameter passing—in mode, out mode, and inout mode—and a number of approaches to implement them. These are pass-by-value, pass-by-result, pass-by-value-result, pass-by-reference, and pass-by-name. In most languages, parameters are passed in the run-time stack.

Aliasing can occur when pass-by-reference parameters are used, both among two or more parameters and between a parameter and an accessible nonlocal variable.

Parameters that are multidimensioned arrays pose some issues for the

language designer, because the called subprogram needs to know how to compute the storage mapping function for them. This requires more than just the name of the array.

Parameters that are subprogram names provide a necessary service but can be difficult to understand. The opacity lies in the referencing environment that is available when a subprogram that has been passed as a parameter is executed.

C and C++ support pointers to functions. C# has delegates, which are objects that can store references to methods. Delegates can support multicast calls by storing more than one method reference.

Ada, C++, C#, Ruby, and Python allow both subprogram and operator overloading. Subprograms can be overloaded as long as the various versions can be disambiguated by the types of their parameters or returned values. Function definitions can be used to build additional meanings for operators.

Subprograms in C++, Java 5.0, and C# 2005 can be generic, using parametric polymorphism, so the desired types of their data objects can be passed to the compiler, which then can construct units for the requested types.

The designer of a function facility in a language must decide what restrictions will be placed on the returned values, as well as the number of return values.

A closure is a subprogram and its referencing environment. Closures are useful in languages that allow nested subprograms, are static-scoped, and allow subprograms to be returned from functions and assigned to variables.

A coroutine is a special subprogram that has multiple entries. It can be used to provide interleaved execution of subprograms.

REVIEW QUESTIONS

1. What are the three general characteristics of subprograms?
2. What does it mean for a subprogram to be active?
3. What is given in the header of a subprogram?
4. What characteristic of Python subprograms sets them apart from those of other languages?
5. What languages allow a variable number of parameters?
6. What is a Ruby array formal parameter?
7. What is a parameter profile? What is a subprogram protocol?
8. What are formal parameters? What are actual parameters?
9. What are the advantages and disadvantages of keyword parameters?
10. What are the differences between a function and a procedure?
11. What are the design issues for subprograms?
12. What are the advantages and disadvantages of dynamic local variables?
13. What are the advantages and disadvantages of static local variables?
14. What languages allow subprogram definitions to be nested?
15. What are the three semantics models of parameter passing?
16. What are the modes, the conceptual models of transfer, the advantages, and the disadvantages of pass-by-value, pass-by-result, pass-by-value-result, and pass-by-reference parameter-passing methods?

17. Describe the ways that aliases can occur with pass-by-reference parameters.

18. What is the difference between the way original C and C89 deal with an actual parameter whose type is not identical to that of the corresponding formal parameter?

19. What are two fundamental design considerations for parameter-passing methods?

20. Describe the problem of passing multidimensioned arrays as parameters.

21. What is the name of the parameter-passing method used in Ruby?

22. What are the two issues that arise when subprogram names are parameters?

23. Define *shallow* and *deep binding* for referencing environments of subprograms that have been passed as parameters.

24. What is an overloaded subprogram?

25. What is parametric polymorphism?

26. What causes a C++ template function to be instantiated?

27. In what fundamental ways do the generic parameters to a Java 5.0 generic method differ from those of C++ methods?

28. If a Java 5.0 method returns a generic type, what type of object is actually returned?

29. If a Java 5.0 generic method is called with three different generic parameters, how many versions of the method will be generated by the compiler?

30. What are the design issues for functions?

31. Name two languages that allow multiple values to be returned from a

function.

32. What exactly is a delegate?
33. What is the main drawback of generic functions in F#?
34. What is a closure?
35. What are the language characteristics that make closures useful?
36. What languages allow the user to overload operators?
37. In what ways are coroutines different from conventional subprograms?

PROBLEM SET

1. What are arguments for and against a user program building additional definitions for existing operators, as can be done in Python and C++? Do you think such user-defined operator overloading is good or bad? Support your answer.

2. In most Fortran IV implementations, all parameters were passed by reference, using access path transmission only. State both the advantages and disadvantages of this design choice.

3. Argue in support of the Ada 83 designers' decision to allow the implementor to choose between implementing **`inout-`**mode parameters by copy or by reference.

4. Suppose you want to write a method that prints a heading on a new output page, along with a page number that is 1 in the first activation and that increases by 1 with each subsequent activation. Can this be done without parameters and without reference to nonlocal variables in Java? Can it be done in C#?

5. Consider the following program written in C syntax:

```
void swap(int a, int b) {
  int temp;
  temp = a;
  a = b;
  b = temp;
}
void main() {
  int value = 2, list[5] = {1, 3, 5, 7, 9};
  swap(value, list[0]);
  swap(list[0], list[1]);
  swap(value, list[value]);
}
```

   For each of the following parameter-passing methods, what are all of the values of the variables `value` and `list` after each of the three calls to

`swap`?

   1. Passed by value

   2. Passed by reference

   3. Passed by value-result

6. Present one argument against providing both static and dynamic local variables in subprograms.

7. Consider the following program written in C syntax:

```
void fun (int first, int second) {
  first += first;
  second += second;
}
void main() {
  int list[2] = {1, 3};
  fun(list[0], list[1]);
}
```

   For each of the following parameter-passing methods, what are the values of the `list` array after execution?

   1. Passed by value

   2. Passed by reference

   3. Passed by value-result

8. Argue against the C design of providing only function subprograms.

9. From a textbook on Fortran, learn the syntax and semantics of statement functions. Justify their existence in Fortran.

10. Study the methods of user-defined operator overloading in C++ and Ada, and write a report comparing the two using our criteria for evaluating languages.

11. C# supports out-mode parameters, but neither Java nor C++ does.

Explain the difference.

12. Research Jensen's Device, which was a use of pass-by-name parameters, and write a short description of what it is and how it can be used.

13. Study the iterator mechanisms of Ruby and CLU and list their similarities and differences.

14. Speculate on the issue of allowing nested subprograms in programming languages—why are they not allowed in many contemporary languages?

15. What are at least two arguments against the use of pass-by-name parameters?

16. Write a detailed comparison of the generic subprograms of Java 5.0 and C# 2005.

PROGRAMMING EXERCISES

1. Write a program in a language that you know to determine the ratio of the time required to pass a large array by reference and the time required to pass the same array by value. Make the array as large as possible on the machine and implementation you use. Pass the array as many times as necessary to get reasonably accurate timings of the passing operations.

2. Write a C# or Ada program that determines when the address of an out-mode parameter is computed (at the time of the call or at the time the execution of the subprogram finishes).

3. Write a Perl program that passes by reference a literal to a subprogram, which attempts to change the parameter. Given the overall design philosophy of Perl, explain the results.

4. Repeat Programming Exercise 3 in C#.

5. Write a program in some language that has both static and stack-dynamic local variables in subprograms. Create six large (at least 100×100) matrices in the subprogram—three static and three stack dynamic. Fill two of the static matrices and two of the stack-dynamic matrices with random numbers in the range of 1 to 100. The code in the subprogram must perform a large number of matrix multiplication operations on the static matrices and time the process. Then it must repeat this with the stack-dynamic matrices. Compare and explain the results.

6. Write a C# program that includes two methods that are called a large number of times. Both methods are passed a large array, one by value and one by reference. Compare the times required to call these two methods and explain the difference. Be sure to call them a sufficient number of times to illustrate a difference in the required time.

7. Write a program, using the syntax of whatever language you like, that produces different behavior depending on whether pass-by-reference or pass-by-value-result is used in its parameter passing.

8. Write a generic C++ function that takes an array of generic elements and a scalar of the same type as the array elements. The type of the array elements and the scalar is the generic parameter. The function must search the given array for the given scalar and return the subscript of the scalar in the array. If the scalar is not in the array, the function must return `-1`. Test the function for `int` and `float` types.

9. Devise a subprogram and calling code in which pass-by-reference and pass-by-value-result of one or more parameters produces different results.

10 Implementing Subprograms

The purpose of this chapter is to explore the implementation of subprograms. The discussion will provide the reader with some knowledge of how subprogram linkage works, and also why ALGOL 60 was a challenge to the unsuspecting compiler writers of the early 1960s. We begin with the simplest situation, nonnestable subprograms with static local variables, advance to more complicated subprograms with stack-dynamic local variables, and conclude with nested subprograms with stack-dynamic local variables and static scoping. The increased difficulty of implementing subprograms in languages with nested subprograms is caused by the need to include mechanisms to access nonlocal variables.

The static chain method of accessing nonlocals in static-scoped languages is discussed in detail. Then, techniques for implementing blocks are described. Finally, several methods of implementing nonlocal variable access in a dynamic-scoped language are discussed.

10.1 The General Semantics of Calls and Returns

The subprogram call and return operations are together called **subprogram linkage**. The implementation of subprograms must be based on the semantics of the subprogram linkage of the language being implemented.

A subprogram call in a typical language has numerous actions associated with it. The call process must include the implementation of whatever -parameter-passing method is used. If local variables are not static, the call process must allocate storage for the locals declared in the called subprogram and bind those variables to that storage. It must save the execution status of the calling program unit. The execution status is everything needed to resume execution of the calling program unit. This includes register values, CPU status bits, and the environment pointer (EP). The EP, which is discussed further in Section 10.3, is used to access parameters and local variables during the execution of a subprogram. The calling process also must arrange to transfer control to the code of the subprogram and ensure that control can return to the proper place when the subprogram execution is completed. Finally, if the language supports nested subprograms, the call process must create some mechanism to provide access to nonlocal variables that are visible to the called subprogram.

The required actions of a subprogram return are less complicated than those of a call. If the subprogram has parameters that are out mode or inout mode and are implemented by copy, the first action of the return process is to move the local values of the associated formal parameters to the actual parameters. Next, it must deallocate the storage used for local variables and restore the execution status of the calling program unit. Finally, control must be returned to the calling program unit.

10.2 Implementing “Simple” Subprograms

We begin with the task of implementing simple subprograms. By “simple” we mean that subprograms cannot be nested and all local variables are static. Early versions of Fortran were examples of languages that had this kind of subprograms.

The semantics of a call to a “simple” subprogram requires the following actions:

1. Save the execution status of the current program unit.
2. Compute and pass the parameters.
3. Pass the return address to the called.
4. Transfer control to the called.

The semantics of a return from a simple subprogram requires the following actions:

1. If there are pass-by-value-result or out-mode parameters, the current values of those parameters are moved to or made available to the corresponding actual parameters.
2. If the subprogram is a function, the functional value is moved to a place accessible to the caller.
3. The execution status of the caller is restored.
4. Control is transferred back to the caller.

The call and return actions require storage for the following:

- Status information about the caller
- Parameters
- Return address
- Return value for functions
- Temporaries used by the code of the subprograms

These, along with the local variables and the subprogram code, form the complete collection of information a subprogram needs to execute and then return control to the caller.

The question now is the distribution of the call and return actions to the caller and the called. For simple subprograms, the answer is obvious for most of the parts of the process. The last three actions of a call clearly must be done by the caller. Saving the execution status of the caller could be done by either. In the case of the return, the first, third, and fourth actions must be done by the called. Once again, the restoration of the execution status of the caller could be done by either the caller or the called. In general, the linkage actions of the called can occur at two different times, either at the beginning of its execution or at the end. These are sometimes called the **prologue** and **epilogue** of the subprogram linkage. In the case of a simple subprogram, all of the linkage actions of the callee occur at the end of its execution, so there is no need for a prologue.

A simple subprogram consists of two separate parts: the actual code of the subprogram, which is constant, and the local variables and data listed previously, which can change when the subprogram is executed. In the case of simple subprograms, both of these parts have fixed sizes.

The format, or layout, of the noncode part of a subprogram is called an **activation record**, because the data it describes are relevant only during the activation or execution of the subprogram. The form of an activation record is static. An **activation record instance** is a concrete example of an activation record, a collection of data in the form of an activation record.

Because languages with simple subprograms do not support recursion, there can be only one active version of a given subprogram at a time. Therefore, there can be only a single instance of the activation record for a subprogram. One possible layout for activation records is shown in Figure 10.1. The saved execution status of the caller is omitted here and in the remainder of this chapter because it is simple and not relevant to the discussion.

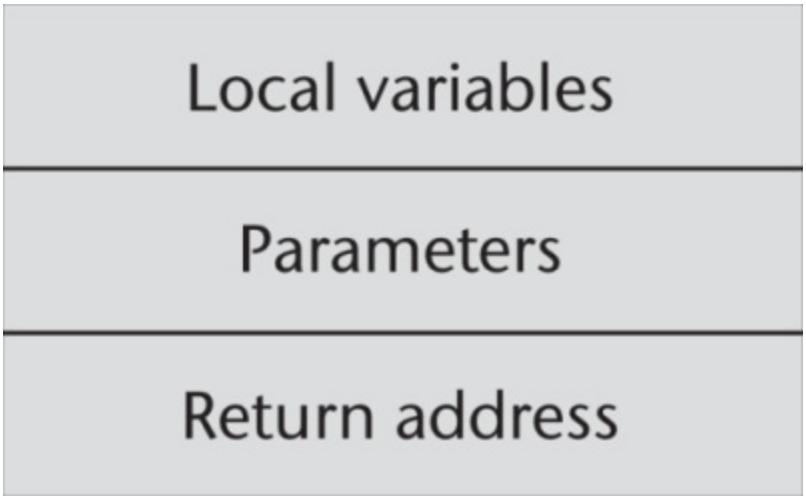

Figure 10.1 An activation record for simple subprogram

Because an activation record instance for a “simple” subprogram has fixed size, it can be statically allocated. In fact, it could be attached to the code part of the subprogram.

Figure 10.2 shows a program consisting of a main program and three subprograms: A, B, and C. Although the figure shows all the code segments separated from all the activation record instances, in some cases, the activation record instances are attached to their associated code segments.

Figure 10.2 Full Alternative Text

The construction of the complete program shown in Figure 10.2 is not done entirely by the compiler. In fact, if the language allows independent compilation, the four program units—`MAIN`, `A`, `B`, and `C`—may have been compiled on different days, or even in different years. At the time each unit is compiled, the machine code for it, along with a list of references to external subprograms, is written to a file. The executable program shown in Figure 10.2 is put together by the **linker**, which is part of the operating system. (Sometimes linkers are called *loaders*, *linker/loaders*, or *link editors*.) When the linker is called for a main program, its first task is to find the files that contain the translated subprograms referenced in that program and load them into memory. Then, the linker must set the target addresses of all calls to those subprograms in the main program to the entry addresses of those subprograms. The same must be done for all calls to subprograms in the loaded subprograms and all calls to library subprograms. In the previous example, the linker was called for `MAIN`. The linker had to find the machine code programs for `A`, `B`, and `C`, along with their activation record instances, and load them into memory with the code for `MAIN`. Then, it had to patch in the target addresses for all calls to `A`, `B`, `C`, and any library subprograms called in `A`, `B`, `C`, and `MAIN`.

10.3 Implementing Subprograms with Stack-Dynamic Local Variables

We now examine the implementation of the subprogram linkage in languages in which locals are stack dynamic, again focusing on the call and return operations.

One of the most important advantages of stack-dynamic local variables is support for recursion. Therefore, languages that use stack-dynamic local variables also support recursion.

A discussion of the additional complexity required when subprograms can be nested is postponed until Section 10.4.

10.3.1 More Complex Activation Records

Subprogram linkage in languages that use stack-dynamic local variables are more complex than the linkage of simple subprograms for the following reasons:

- The compiler must generate code to cause the implicit allocation and deallocation of local variables.
- Recursion adds the possibility of multiple simultaneous activations of a subprogram, which means that there can be more than one instance (incomplete execution) of a subprogram at a given time, with at least one call from outside the subprogram and one or more recursive calls. The number of activations is limited only by the memory size of the

machine. Each activation requires its own activation record instance.

The format of an activation record for a given subprogram in most languages is known at compile time. In many cases, the size is also known for activation records because all local data are of a fixed size. That is not the case in some other languages, such as Ada, in which the size of a local array can depend on the value of an actual parameter. In those cases, the format is static, but the size can be dynamic. In languages with stack-dynamic local variables, activation record instances must be created dynamically. The typical activation record for such a language is shown in Figure 10.3.

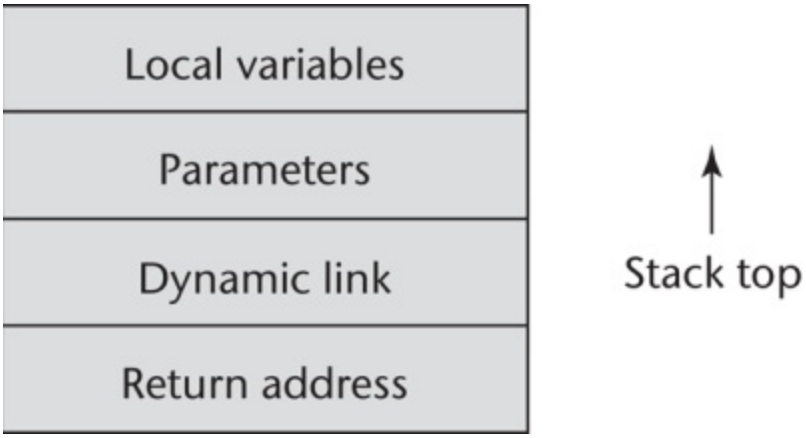

Figure 10.3 A typical activation record for a language with stack-dynamic local variables

Because the return address, dynamic link, and parameters are placed in the activation record instance by the caller, these entries must appear first.

The return address usually consists of a pointer to the instruction following the call in the code segment of the calling program unit. The **dynamic link** is a pointer to the base of the activation record instance of the caller. In static-scoped languages, this link is used to provide traceback information when a run-time error occurs. In dynamic-scoped languages, the dynamic link is used to access nonlocal variables. The actual parameters in the activation record

are the values or addresses provided by the caller.

Local scalar variables are bound to storage within an activation record instance. Local variables that are structures are sometimes allocated elsewhere, and only their descriptors and a pointer to that storage are part of the activation record. Local variables are allocated and possibly initialized in the called subprogram, so they appear last.

Consider the following skeletal C function:

```
void sub(float total, int part) {
  int list[5];
  float sum;
  . . .
}
```

The activation record for `sub` is shown in Figure 10.4.

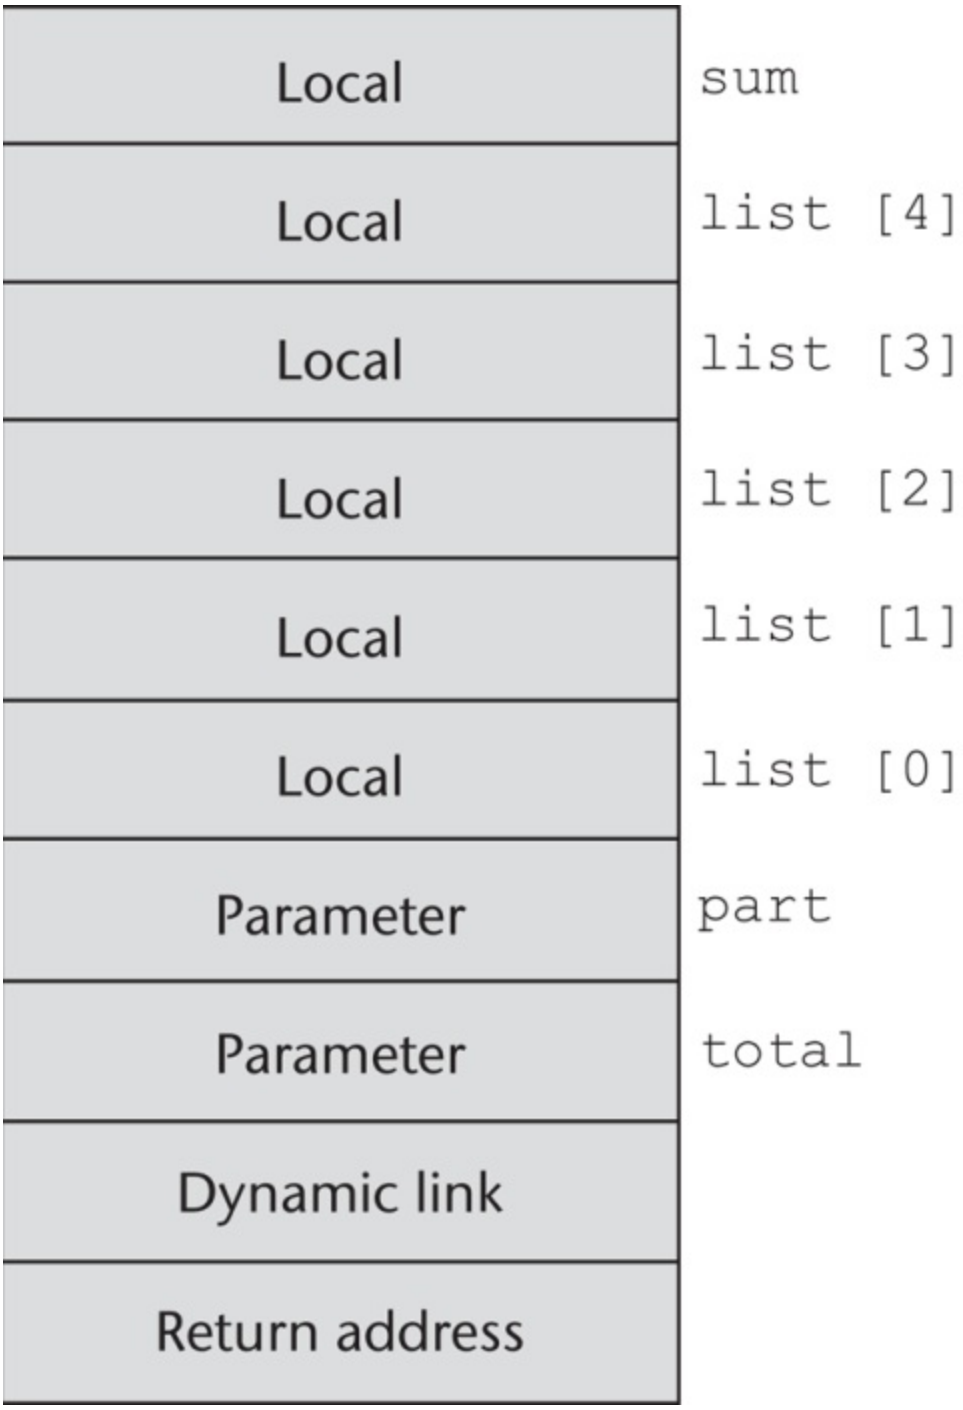

Figure 10.4 The activation record for function sub

Figure 10.4 Full Alternative Text

Activating a subprogram requires the dynamic creation of an instance of the activation record for the subprogram. As stated earlier, the format of the activation record is fixed at compile time, although its size may depend on the call in some languages. Because the call and return semantics specify that the subprogram last called is the first to complete, it is reasonable to create instances of these activation records on a stack. This stack is part of the run-time system and therefore is called the **run-time stack**, although we will usually just refer to it as the stack. Every subprogram activation, whether recursive or nonrecursive, creates a new instance of an activation record on the stack. This provides the required separate copies of the parameters, local variables, and return address.

One more thing is required to control the execution of a subprogram—the EP. Initially, the EP points at the base, or first address of the activation record instance of the main program. The run-time system must ensure that it always points at the base of the activation record instance of the currently executing program unit. When a subprogram is called, the current EP is saved in the new activation record instance as the dynamic link. The EP is then set to point at the base of the new activation record instance. Upon return from the subprogram, the stack top is set to the value of the current EP minus one and the EP is set to the dynamic link from the activation record instance of the subprogram that has completed its execution. Resetting the stack top effectively removes the top activation record instance.

The EP is used as the base of the offset addressing of the data contents of the activation record instance—parameters and local variables.

Note that the EP currently being used is not stored in the run-time stack. Only saved versions are stored in the activation record instances as the dynamic links.

We have now discussed several new actions in the linkage process. The lists given in Section 10.2 must be revised to take these into account. Using the activation record form given in this section, the new actions are as follows:

The caller actions are as follows:

1. Create an activation record instance.
2. Save the execution status of the current program unit.
3. Compute and pass the parameters.
4. Pass the return address to the called.
5. Transfer control to the called.

The prologue actions of the called are as follows:

1. Save the old EP in the stack as the dynamic link and create the new value.
2. Allocate local variables.

The epilogue actions of the called are as follows:

1. If there are pass-by-value-result or out-mode parameters, the current values of those parameters are moved to the corresponding actual parameters.
2. If the subprogram is a function, the functional value is moved to a place accessible to the caller.
3. Restore the stack pointer by setting it to the value of the current EP minus one and set the EP to the old dynamic link.
4. Restore the execution status of the caller.
5. Transfer control back to the caller.

Recall from Chapter 9, that a subprogram is **active** from the time it is called until the time that execution is completed. At the time it becomes inactive, its local scope ceases to exist and its referencing environment is no longer meaningful. Therefore, at that time, its activation record instance can be destroyed.

Parameters are not always transferred in the stack. In many compilers for RISC machines, parameters are passed in registers. This is because RISC machines normally have many more registers than CISC machines. In the remainder of this chapter, however, we assume that parameters are passed in the stack. It is straightforward to modify this approach for parameters being passed in registers.

10.3.2 An Example without Recursion

Consider the following skeletal C program:

```
void fun1(float r) {
  int s, t;
  . . .    <---------- 1
  fun2(s);
  . . .
}
void fun2(int x) {
  int y;
  . . .    <---------- 2
  fun3(y);
  . .
}
void fun3(int q) {
  . . .    <---------- 3
}
void main() {
  float p;
  . . .
  fun1(p);
  . . .
}
```

The sequence of function calls in this program is

```
main calls fun1
fun1 calls fun2
fun2 calls fun3
```

The stack contents for the points labeled 1, 2, and 3 are shown in Figure 10.5.

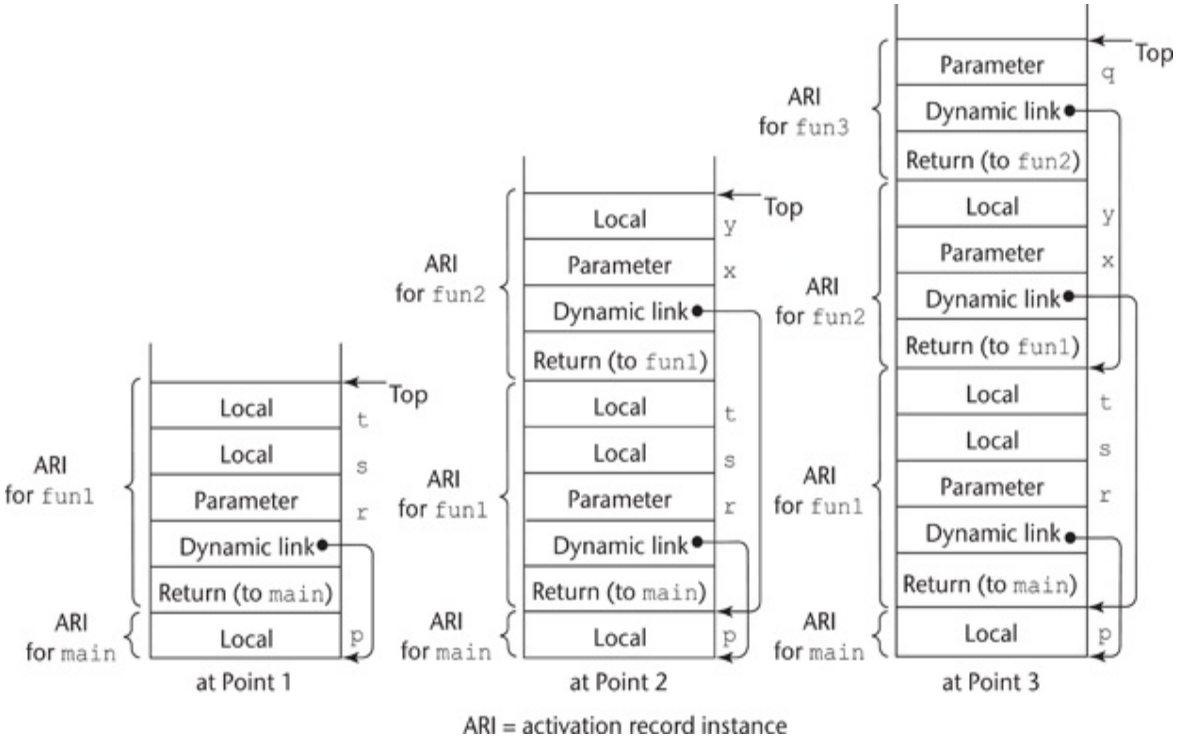

Figure 10.5 Stack contents for three points in a program

Figure 10.5 Full Alternative Text

At point 1, only the activation record instances for function `main` and function `fun1` are on the stack. When `fun1` calls `fun2`, an instance of `fun2`'s activation record is created on the stack. When `fun2` calls `fun3`, an instance of `fun3`'s activation record is created on the stack. When `fun3`'s execution ends, the instance of its activation record is removed from the stack, and the EP is used to reset the stack top pointer. Similar processes take place when functions `fun2` and `fun1` terminate. After the return from the call to `fun1` from `main`, the stack has only the instance of the activation record of `main`. Note that some implementations do not actually use an activation record instance on the stack for main functions, such as the one shown in the figure. However, it can be done this way, and it simplifies both the implementation and our discussion.

In this example and in all others in this chapter, we assume that the stack grows from lower addresses to higher addresses, although in a particular implementation, the stack may grow in the opposite direction.

The collection of dynamic links present in the stack at a given time is called the **dynamic chain**, or **call chain**. It represents the dynamic history of how execution got to its current position, which is always in the subprogram code whose activation record instance is on top of the stack. References to local variables can be represented in the code as offsets from the beginning of the activation record of the local scope, whose address is stored in the EP. Such an offset is called a **local_offset**.

The local_offset of a variable in an activation record can be determined at compile time, using the order, types, and sizes of variables declared in the subprogram associated with the activation record. To simplify the discussion, we assume that all variables take one position in the activation record. The first local variable declared in a subprogram would be allocated in the activation record two positions plus the number of parameters from the bottom (the first two positions are for the return address and the dynamic link). The second local variable declared would be one position nearer the stack top and so forth. For example, consider the preceding example program. In `fun1`, the local_offset of `s` is 3; for `t` it is 4. Likewise, in `fun2`, the local_offset of `y` is 3. To get the address of any local variable, the local_offset of the variable is added to the EP.

10.3.3 Recursion

Consider the following example C program, which uses recursion to compute the factorial function:

```
int factorial(int n) {
    <---------- 1
  if (n <= 1)
    return 1;
  else return (n * factorial(n - 1));
    <---------- 2
 }
void main() {
```

```
  int value;
  value = factorial(3);
    <---------- 3
}
```

The activation record format for the function `factorial` is shown in Figure 10.6. Notice that it has an additional entry for the return value of the function.

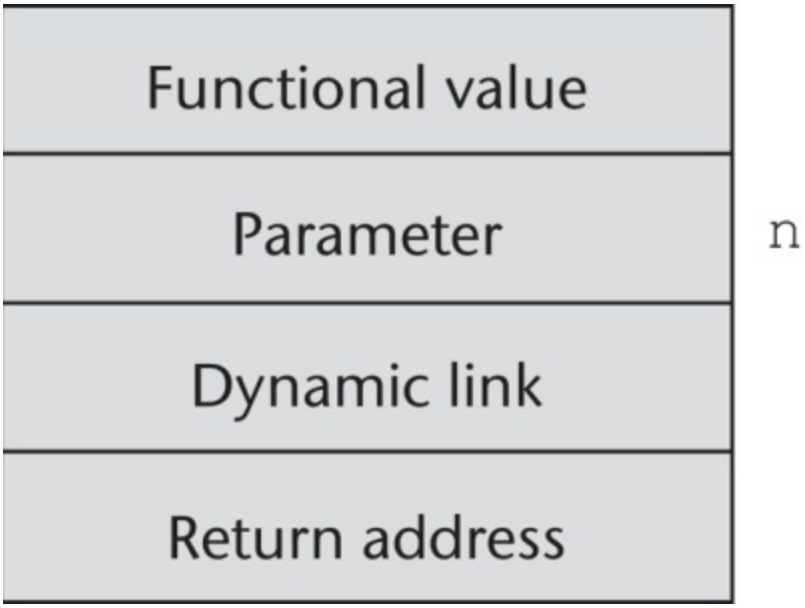

Figure 10.6 The activation record for `factorial`

Figure 10.7 shows the contents of the stack for the three times execution reaches position 1 in the function `factorial`. Each shows one more activation of the function, with its functional value undefined. The first activation record instance has the return address to the calling function, `main`. The others have a return address to the function itself; these are for the recursive calls.

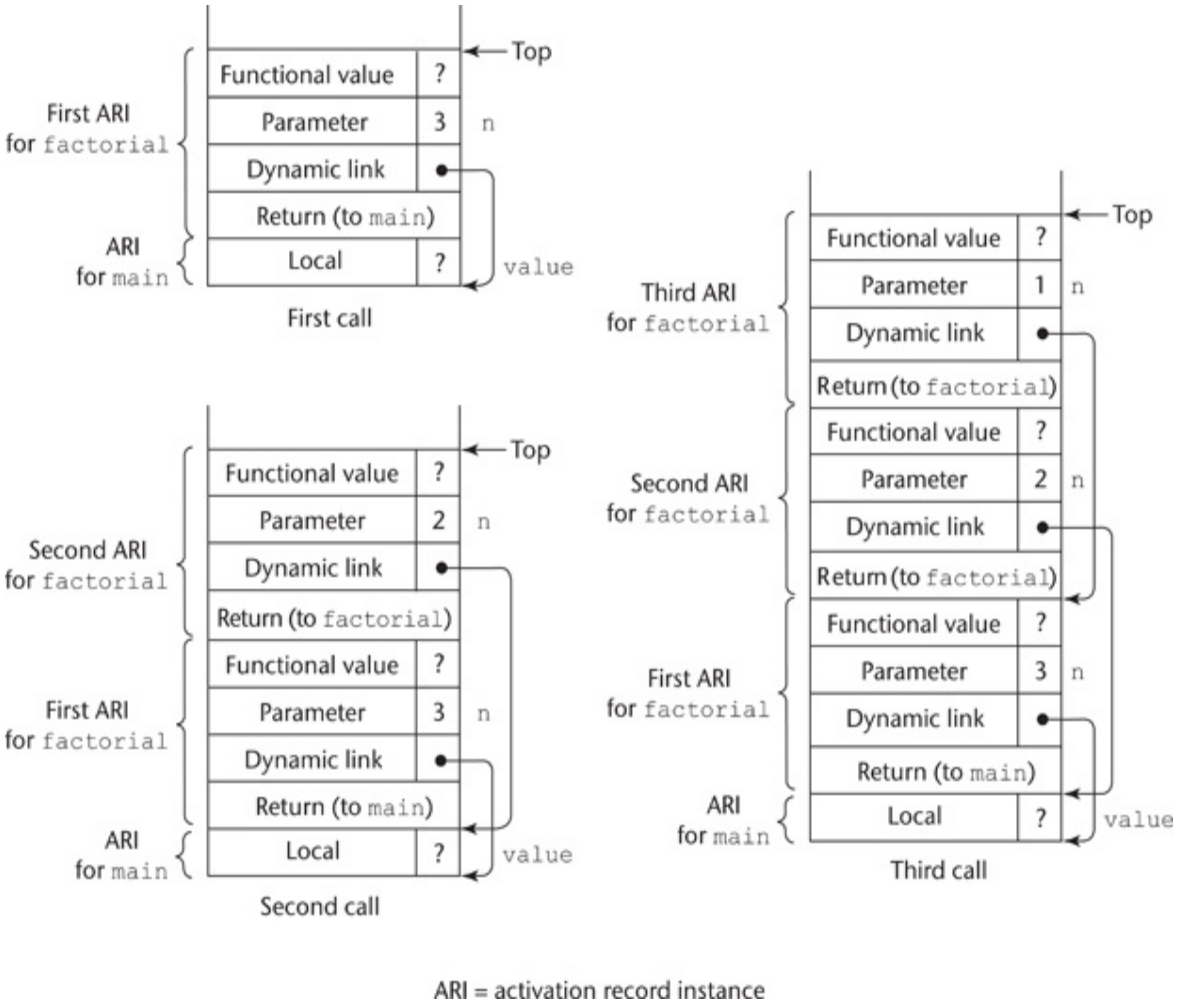

Figure 10.7 Stack contents at position 1 in `factorial`

Figure 10.7 Full Alternative Text

Figure 10.8 shows the stack contents for the three times that execution reaches position 2 in the function `factorial`. Position 2 is meant to be the time after the **`return`** is executed but before the activation record has been removed from the stack. Recall that the code for the function multiplies the current value of the parameter `n` by the value returned by the recursive call to the function. The first return from `factorial` returns the value 1. The activation record instance for that activation has a value of 1 for its version of

the parameter `n`. The result from that multiplication, 1, is returned to the second activation of `factorial` to be multiplied by its parameter value for `n`, which is 2. This step returns the value 2 to the first activation of `factorial` to be multiplied by its parameter value for `n`, which is 3, yielding the final functional value of 6, which is then returned to the first call to `factorial` in `main`.

10.4 Nested Subprograms

Some of the non–C-based static-scoped programming languages use stack--dynamic local variables and allow subprograms to be nested. Among these are Fortran 95+, Ada, Python, JavaScript, Ruby, and Swift, as well as the functional languages. In this section, we examine the most commonly used approach to implementing subprograms that may be nested. Until the very end of this section, we ignore closures.

10.4.1 The Basics

A reference to a nonlocal variable in a static-scoped language with nested subprograms requires a two-step access process. All nonstatic variables that can be nonlocally accessed are in existing activation record instances and therefore are somewhere in the stack. The first step of the access process is to find the instance of the activation record in the stack in which the variable was allocated. The second part is to use the local_offset of the variable (within the activation record instance) to access it.

Finding the correct activation record instance is the more interesting and more difficult of the two steps. First, note that in a given subprogram, only variables that are declared in static ancestor scopes are visible and can be accessed. Also, activation record instances of all of the static ancestors are always on the stack when variables in them are referenced by a nested subprogram. This is guaranteed by the static semantic rules of the static-scoped languages: A subprogram is callable only when all of its static ancestor subprograms are active.1 If a particular static ancestor were not active, its local variables would not be bound to storage, so it would be nonsense to allow access to them.

1. Closures, of course, violate this rule.

The semantics of nonlocal references dictates that the correct declaration is the first one found when looking through the enclosing scopes, most closely

nested first. So, to support nonlocal references, it must be possible to find all of the instances of activation records in the stack that correspond to those static ancestors. This observation leads to the implementation approach described in the following subsection.

We do not address the issue of blocks until Section 10.5, so in the remainder of this section, all scopes are assumed to be defined by subprograms. Because functions cannot be nested in the C-based languages (the only static scope in those languages are those created with blocks), the discussions of this section do not apply to those languages directly.

10.4.2 Static Chains

The most common way to implement static scoping in languages that allow nested subprograms is static chaining. In this approach, a new pointer, called a static link, is added to the activation record. The **static link**, which is sometimes called a *static scope pointer*, points to the bottom of the activation record instance of an activation of the static parent. It is used for accesses to nonlocal variables. Typically, the static link appears in the activation record below the parameters. The addition of the static link to the activation record requires that local offsets differ from when the static link is not included. Instead of having two activation record elements before the parameters, there are now three: the return address, the static link, and the dynamic link.

A **static chain** is a chain of static links that connect certain activation record instances in the stack. During the execution of a subprogram `P`, the static link of its activation record instance points to an activation record instance of `P`'s static parent program unit. That instance's static link points in turn to `P`'s static grandparent program unit's activation record instance, if there is one. So, the static chain connects all the static ancestors of an executing subprogram, in order of static parent first. This chain can obviously be used to implement the accesses to nonlocal variables in static-scoped languages.

Finding the correct activation record instance of a nonlocal variable using static links is relatively straightforward. When a reference is made to a nonlocal variable, the activation record instance containing the variable can

be found by searching the static chain until a static ancestor activation record instance is found that contains the variable. However, it can be much easier than that. Because the nesting of scopes is known at compile time, the compiler can determine not only that a reference is nonlocal but also the length of the static chain that must be followed to reach the activation record instance that contains the nonlocal object.

Let **static_depth** be an integer associated with a static scope that indicates how deeply it is nested in the outermost scope. A program unit that is not nested inside any other unit has a static_depth of 0. If subprogram `A` is defined in a nonnested program unit, its static_depth is 1. If subprogram `A` contains the definition of a nested subprogram `B`, then `B`'s static_depth is 2.

The length of the static chain needed to reach the correct activation record instance for a nonlocal reference to a variable `X` is exactly the difference between the static_depth of the subprogram containing the reference to `X` and the static_depth of the subprogram containing the declaration for `X`. This difference is called the **nesting_depth**, or **chain_offset**, of the reference. The actual reference can be represented by an ordered pair of integers (chain_offset, local_offset), where chain_offset is the number of links to the correct activation record instance (local_offset is described in Section 10.3.2). For example, consider the following skeletal Python program:

```
# Global scope
. . .
def f1():
  def f2():
    def f3():
      . . .
    # end of f3
    . . .
  # end of f2
  . .
# end of f1
```

The static_depths of the global scope, `f1`, `f2`, and `f3` are 0, 1, 2, and 3, respectively. If procedure `f3` references a variable declared in `f1`, the chain_offset of that reference would be 2 (static_depth of `f3` minus the static_depth of `f1`). If procedure `f3` references a variable declared in `f2`, the chain_offset of that reference would be 1. References to locals can be

handled using the same mechanism, with a chain_offset of 0, but instead of using the static pointer to the activation record instance of the subprogram where the variable was declared as the base address, the EP is used.

To illustrate the complete process of nonlocal accesses, consider the - following skeletal JavaScript program:

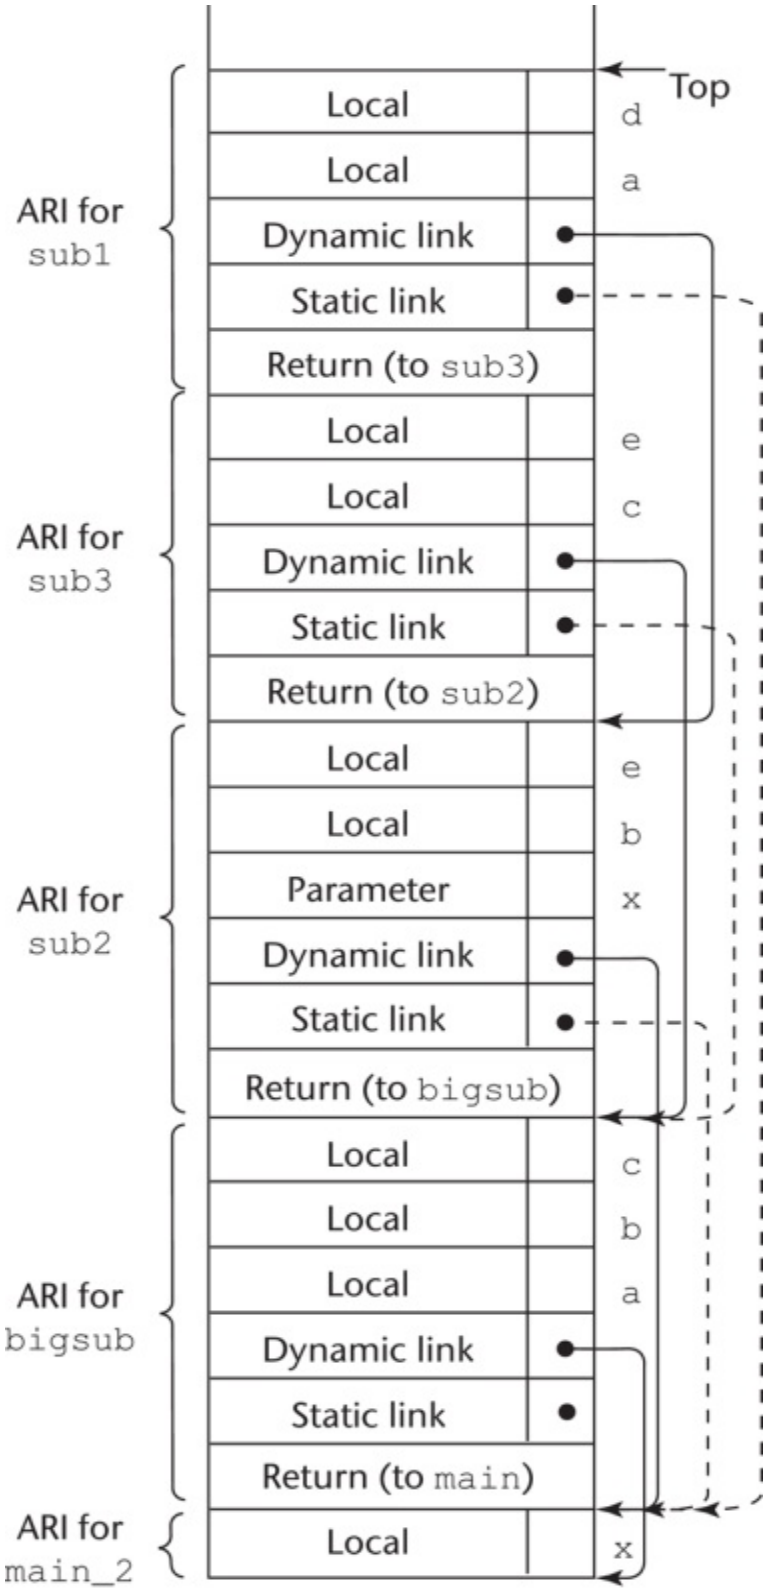
```
function main(){
  var x;
  function bigsub() {
    var a, b, c;
    function sub1 {
      var a, d;
      ...
      a = b + c; <---------------------------------1
      ...
    }  // end of sub1
    function sub2(x) {
      var b, e;
      function sub3() {
        var c, e;
        ...
        sub1();
        ...
        e = b + a; <---------------------------------2
      } // end of sub3
      ...
      sub3();
      ...
      a = d + e; <---------------------------------3
    } // end of sub2
    ...
    sub2(7);
    ...
  } // end of bigsub
  ...
  bigsub();
  ...
} // end of main
```

The sequence of procedure calls is

- `main` calls `bigsub`
- `bigsub` calls `sub2`

- `sub2` calls `sub3`
- `sub3` calls `sub1`

The stack situation when execution first arrives at point 1 in this program is shown in Figure 10.9.



ARI = activation record instance

Figure 10.9 Stack contents at - position 1 in the program `main`

Figure 10.9 Full Alternative Text

At position 1 in procedure `sub1`, the reference is to the local variable, `a`, not to the nonlocal variable `a` from `bigsub`. This reference to `a` has the chain_offset/local_offset pair (0, 3). The reference to `b` is to the nonlocal `b` from `bigsub`. It can be represented by the pair (1, 4). The local_offset is 4, because a 3 offset would be the first local variable (`bigsub` has no parameters). Notice that if the dynamic link were used to do a simple search for an activation record instance with a declaration for the variable `b`, it would find the variable `b` declared in `sub2`, which would be incorrect. If the (1, 4) pair were used with the dynamic chain, the variable `e` from `sub3` would be used. The static link, however, points to the activation record for `bigsub`, which has the correct version of `b`. The variable `b` in `sub2` is not in the referencing environment at this point and is (correctly) not accessible. The reference to `c` at point 1 is to the `c` defined in `bigsub`, which is represented by the pair (1, 5).

After `sub1` completes its execution, the activation record instance for `sub1` is removed from the stack, and control returns to `sub3`. The reference to the variable `e` at position 2 in `sub3` is local and uses the pair (0, 4) for access. The reference to the variable `b` is to the one declared in `sub2`, because that is the nearest static ancestor that contains such a declaration. It is accessed with the pair (1, 4). The local_offset is 4 because `b` is the first variable declared in `sub1`, and `sub2` has one parameter. The reference to the variable `a` is to the `a` declared in `bigsub`, because neither `sub3` nor its static parent `sub2` has a declaration for a variable named `a`. It is referenced with the pair (2, 3).

After `sub3` completes its execution, the activation record instance for `sub3` is removed from the stack, leaving only the activation record instances for `main`, `bigsub`, and `sub2`. At position 3 in `sub2`, the reference to the variable `a` is to the `a` in `bigsub`, which has the only declaration of `a` among the active

routines. This access is made with the pair (1, 3). At this position, there is no visible scope containing a declaration for the variable `d`, so this reference to `d` is a static semantics error. The error would be detected when the compiler attempted to compute the chain_offset/local_offset pair. The reference to `e` is to the local `e` in `sub2`, which can be accessed with the pair (0, 5).

In summary, the references to the variable `a` at points 1, 2, and 3 would be represented by the following points:

- (0, 3) (local)
- (2, 3) (two levels away)
- (1, 3) (one level away)

It is reasonable at this point to ask how the static chain is maintained during program execution. If its maintenance is too complex, the fact that it is simple and effective would be unimportant. We assume here that parameters that are subprograms are not implemented.

The static chain must be modified for each subprogram call and return. The return part is trivial: When the subprogram terminates, its activation record instance is removed from the stack. After this removal, the new top activation record instance is that of the unit that called the subprogram whose execution just terminated. Because the static chain from this activation record instance was never changed, it works correctly just as it did before the call to the other subprogram. Therefore, no other action is required.

The action required at a subprogram call is more complex. Although the correct parent scope is easily determined at compile time, the most recent activation record instance of the parent scope must be found at the time of the call. This can be done by looking at activation record instances on the dynamic chain until the first one of the parent scope is found. However, this search can be avoided by treating subprogram declarations and references exactly like variable declarations and references. When the compiler encounters a subprogram call, among other things, it determines the subprogram that declared the called subprogram, which must be a static ancestor of the calling routine. It then computes the nesting_depth, or number

of enclosing scopes between the caller and the subprogram that declared the called subprogram. This information is stored and can be accessed by the subprogram call during execution. At the time of the call, the static link of the called subprogram's activation record instance is found by moving down the static chain of the caller. The number of links in this move is equal to the nesting_depth, which was computed at compile time.

Consider again the program `main` and the stack situation shown in Figure 10.9. At the call to `sub1` in `sub3`, the compiler determines the nesting_depth of `sub3` (the caller) to be two levels inside the procedure that declared the called procedure `sub1`, which is `bigsub`. When the call to `sub1` in `sub3` is executed, this information is used to set the static link of the activation record instance for `sub1`. This static link is set to point to the activation record instance that is pointed to by the second static link in the static chain from the caller's activation record instance. In this case, the caller is `sub3`, whose static link points to its parent's activation record instance (that of `sub2`). The static link of the activation record instance for `sub2` points to the activation record instance for `bigsub`. So, the static link for the new activation record instance for `sub1` is set to point to the activation record instance for `bigsub`.

This method works for all subprogram linkage, except when parameters that are subprograms are involved.

One criticism of using the static chain approach to access nonlocal variables is that references to variables in scopes beyond the static parent cost more than references to locals. The static chain must be followed, one link per enclosing scope from the reference to the declaration. Fortunately, in practice, references to distant nonlocal variables are rare, so this is not a serious problem. Another criticism of the static-chain approach is that it is difficult for a programmer working on a time-critical program to estimate the costs of nonlocal references, because the cost of each reference depends on the depth of nesting between the reference and the scope of declaration. Further complicating this problem is that subsequent code modifications may change nesting depths, thereby changing the timing of some references, both in the changed code and possibly in code far from the changes.

Some alternatives to static chains have been developed, most notably an

approach that uses an auxiliary data structure called a **display**. However, none of the alternatives has been found to be superior to the static-chain method, which is still the most widely used approach. Therefore, none of the alternatives are discussed here.

The processes and data structures described in this section correctly implement closures in languages that do not permit functions to return functions and do not allow functions to be assigned to variables. However, they are inadequate for languages that do allow one or both of those operations. Several new mechanisms are needed to implement access to nonlocals in such languages. First, if a subprogram accesses a variable from a nesting but not global scope, that variable cannot be stored only in the activation record of its home scope. That activation record could be deallocated before the subprogram that needs it is activated. Such variables could also be stored in the heap and given unlimited extend (their lifetimes are the lifetime of the whole program). Second, subprograms must have mechanisms to access the nonlocals that are stored in the heap. Third, the heap-allocated variables that are nonlocally accessed must be updated every time their stack versions are updated. Clearly, these are nontrivial extensions to the implementation static scoping using static chains.

10.5 Blocks

Recall from Chapter 5, that a number of languages, including the C-based languages, provide for user-specified local scopes for variables called **blocks**. As an example of a block, consider the following code segment:

```
{ int temp;
  temp = list[upper];
  list[upper] = list[lower];
  list[lower] = temp;
}
```

A block is specified in the C-based languages as a compound statement that begins with one or more data definitions. The lifetime of the variable `temp` in the preceding block begins when control enters the block and ends when control exits the block. The advantage of using such a local is that it cannot interfere with any other variable with the same name that is declared elsewhere in the program, or more specifically, in the referencing environment of the block.

Blocks can be implemented by using the static-chain process described in Section 10.4 for implementing nested subprograms. Blocks are treated as parameterless subprograms that are always called from the same place in the program. Therefore, every block has an activation record. An instance of its activation record is created every time the block is executed.

Blocks can also be implemented in a different and somewhat simpler and more efficient way. The maximum amount of storage required for block variables at any time during the execution of a program can be statically determined, because blocks are entered and exited in strictly textual order. This amount of space can be allocated after the local variables in the activation record. Offsets for all block variables can be statically computed, so block variables can be addressed exactly as if they were local variables.

For example, consider the following skeletal program:

```
void main() {
```

```
  int x, y, z;
  while ( . . ) {
    int a, b, c;
    .
    while ( . . . ) {
      int d, e;
      .
    }
  }
  while ( . . . ) {
    int f, g;
    . . .
  }
  . .
}
```

For this program, the static-memory layout shown in Figure 10.10 could be used. Note that `f` and `g` occupy the same memory locations as `a` and `b`, because `a` and `b` are popped off the stack when their block is exited (before `f` and `g` are allocated).

10.6 Implementing Dynamic Scoping

There are at least two distinct ways in which local variables and nonlocal references to them can be implemented in a dynamic-scoped language: deep access and shallow access. Note that deep access and shallow access are not concepts related to deep and shallow binding. An important difference between binding and access is that deep and shallow bindings result in different semantics; deep and shallow accesses do not.

10.6.1 Deep Access

If local variables are stack dynamic and are part of the activation records in a dynamic-scoped language, references to nonlocal variables can be resolved by searching through the activation record instances of the other subprograms that are currently active, beginning with the one most recently activated. This concept is similar to that of accessing nonlocal variables in a static-scoped language with nested subprograms, except that the dynamic—rather than the static—chain is followed. The dynamic chain links together all subprogram activation record instances in the reverse of the order in which they were activated. Therefore, the dynamic chain is exactly what is needed to reference nonlocal variables in a dynamic-scoped language. This method is called **deep access**, because access may require searches deep into the stack.

Consider the following example skeletal program:

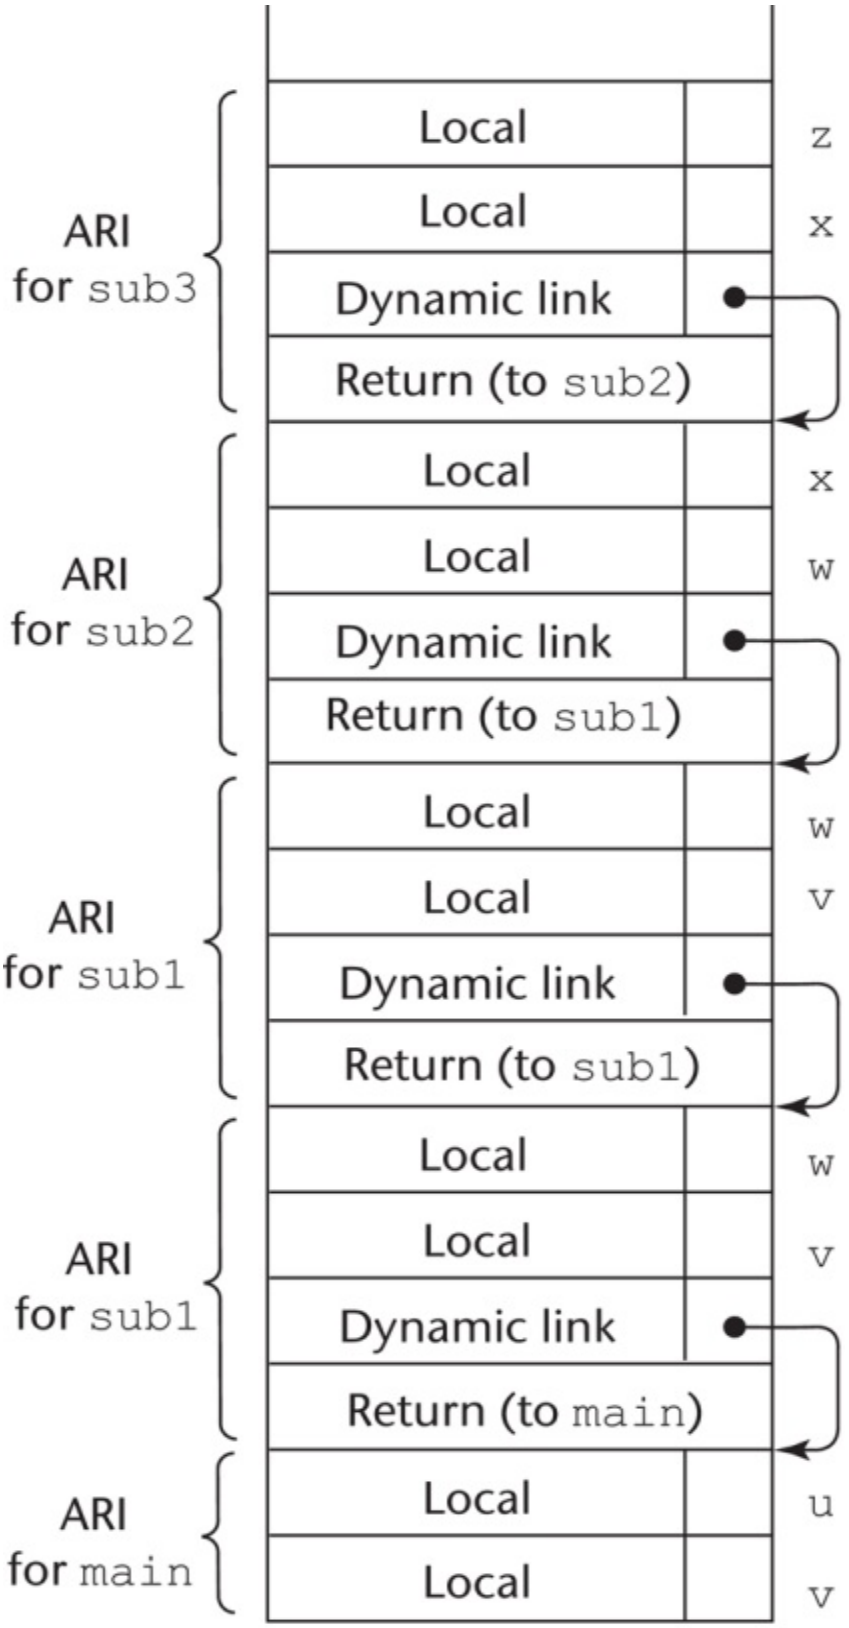
```
void sub3() {
  int x, z;
  x = u + v;
  . . .
}
void sub2() {
  int w, x;
  . . .
```

```
}
void sub1() {
  int v, w;
  . . .
}
void main() {
  int v, u;
  . . .
}
```

This program is written in a syntax that gives it the appearance of a program in a C-based language, but it is not meant to be in any particular language. Suppose the following sequence of function calls occurs:

- `main` calls `sub1`
- `sub1` calls `sub1`
- `sub1` calls `sub2`
- `sub2` calls `sub3`

Figure 10.11 shows the stack during the execution of function `sub3` after this calling sequence. Notice that the activation record instances do not have static links, which would serve no purpose in a dynamic-scoped language.



ARI = activation record instance

Figure 10.11 Stack contents for a dynamic-scoped program

Figure 10.11 Full Alternative Text

Consider the references to the variables `x`, `u`, and `v` in function `sub3`. The reference to `x` is found in the activation record instance for `sub3`. The reference to `u` is found by searching *all* of the activation record instances on the stack, because the only existing variable with that name is in `main`. This search involves following four dynamic links and examining 10 variable names. The reference to `v` is found in the most recent (nearest on the dynamic chain) activation record instance for the subprogram `sub1`.

There are two important differences between the deep-access method for nonlocal access in a dynamic-scoped language and the static-chain method for static-scoped languages. First, in a dynamic-scoped language, there is no way to determine at compile time the length of the chain that must be searched. Every activation record instance in the chain must be searched until the first instance of the variable is found. This is one reason why dynamic-scoped languages typically have slower execution speeds than static-scoped languages. Second, activation records must store the names of variables for the search process, whereas in static-scoped language implementations only the values are required. (Names are not required for static scoping, because all variables are represented by the chain_offset/local_offset pairs.)

10.6.2 Shallow Access

Shallow access is an alternative implementation method, not an alternative semantics. As stated previously, the semantics of deep access and shallow access are identical. In the shallow-access method, variables declared in subprograms are not stored in the activation records of those subprograms. Because with dynamic scoping there is at most one visible version of a

variable of any specific name at a given time, a very different approach can be taken. One variation of shallow access is to have a separate stack for each variable name in a complete program. Every time a new variable with a particular name is created by a declaration at the beginning of a subprogram that has been called, the variable is given a cell at the top of the stack for its name. Every reference to the name is to the variable on top of the stack associated with that name, because the top one is the most recently created. When a subprogram terminates, the lifetimes of its local variables end, and the stacks for those variable names are popped. This method allows fast references to variables, but maintaining the stacks at the entrances and exits of subprograms is costly.

Figure 10.12 shows the variable stacks for the earlier example program in the same situation as shown with the stack in Figure 10.11.

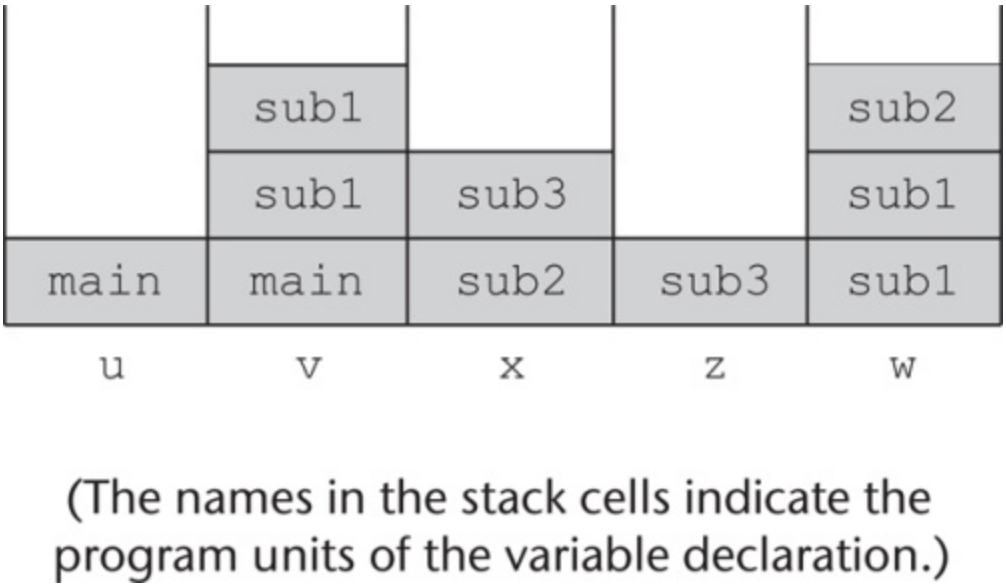


Figure 10.12 One method of using shallow access to - implement dynamic scoping

Figure 10.12 Full Alternative Text

Another option for implementing shallow access is to use a central table that has a location for each different variable name in a program. Along with each entry, a bit called **active** is maintained that indicates whether the name has a current binding or variable association. Any access to any variable can then be to an offset into the central table. The offset is static, so the access can be fast. SNOBOL implementations use the central table implementation technique.

Maintenance of a central table is straightforward. A subprogram call requires that all of its local variables be logically placed in the central table. If the position of the new variable in the central table is already active—that is, if it contains a variable whose lifetime has not yet ended (which is indicated by the active bit)—that value must be saved somewhere during the lifetime of the new variable. Whenever a variable begins its lifetime, the active bit in its central table position must be set.

There have been several variations in the design of the central table and in the way values are stored when they are temporarily replaced. One variation is to have a “hidden” stack on which all saved objects are stored. Because subprogram calls and returns, and thus the lifetimes of local variables, are nested, this works well.

The second variation is perhaps the cleanest and least expensive to implement. A central table of single cells is used, storing only the current version of each variable with a unique name. Replaced variables are stored in the activation record of the subprogram that created the replacement variable. This is a stack mechanism, but it uses the stack that already exists, so the new overhead is minimal.

The choice between shallow and deep access to nonlocal variables depends on the relative frequencies of subprogram calls and nonlocal references. The deep-access method provides fast subprogram linkage, but references to nonlocals, especially references to distant nonlocals (in terms of the call chain), are costly. The shallow-access method provides much faster references to nonlocals, especially distant nonlocals, but is more costly in terms of subprogram linkage.

SUMMARY

Subprogram linkage semantics requires many actions by the implementation. In the case of “simple” subprograms, these actions are relatively uncomplicated. At the call, the status of execution must be saved, parameters and the return address must be passed to the called subprogram, and control must be transferred. At the return, the values of pass-by-result and pass-by-value-result parameters must be transferred back, as well as the return value if it is a function, execution status must be restored, and control transferred back to the caller. In languages with stack-dynamic local variables and nested subprograms, subprogram linkage is more complex. There may be more than one activation record instance, those instances must be stored on the run-time stack, and static and dynamic links must be maintained in the activation record instances. The static link is to allow references to nonlocal variables in static-scoped languages.

Subprograms in languages with stack-dynamic local variables and nested subprograms have two components: the actual code, which is static, and the activation record, which is stack dynamic. Activation record instances contain the formal parameters and local variables, among other things. Access to nonlocal variables is implemented with a chain of static parent pointers.

Access to nonlocal variables in a dynamic-scoped language can be implemented by use of the dynamic chain or through some central variable table method. Dynamic chains provide slow accesses but fast calls and returns. The central table methods provide fast accesses but slow calls and returns.

REVIEW QUESTIONS

1. What is the definition used in this chapter for “simple” subprograms?
2. Which of the caller or callee saves execution status information?
3. What must be stored for the linkage to a subprogram?
4. What is the task of a linker?
5. What are the two reasons why implementing subprograms with stack-dynamic local variables is more difficult than implementing simple subprograms?
6. What is the difference between an activation record and an activation record instance?
7. Why are the return address, dynamic link, and parameters placed in the bottom of the activation record?
8. What kind of machines often use registers to pass parameters?
9. What are the two steps in locating a nonlocal variable in a static-scoped language with stack-dynamic local variables and nested subprograms?
10. Define *static chain*, *static_depth*, *nesting_depth*, and *chain_offset*.
11. What is an EP, and what is its purpose?
12. How are references to variables represented in the static-chain method?
13. Name three widely used programming languages that do not allow nested subprograms.
14. What are the two potential problems with the static-chain method?

15. Explain the two methods of implementing blocks.

16. Describe the deep-access method of implementing dynamic scoping.

17. Describe the shallow-access method of implementing dynamic scoping.

18. What are the two differences between the deep-access method for nonlocal access in dynamic-scoped languages and the static-chain method for static-scoped languages?

19. Compare the efficiency of the deep-access method to that of the shallow-access method, in terms of both calls and nonlocal accesses.

PROBLEM SET

1. Show the stack with all activation record instances, including static and dynamic chains, when execution reaches position 1 in the following skeletal program. Assume `bigsub` is at level 1.

```
function bigsub() {
  function a() {
     function b() {
        ... <----------------------------1
     } // end of b
     function  c() {
       ...
       b();
       ...
     } // end of c
     ...
     c();
     ...
  } // end of a
  ...
  a();
  ...
} // end of bigsub
```

2. Show the stack with all activation record instances, including static and dynamic chains, when execution reaches position 1 in the following skeletal program. Assume `bigsub` is at level 1.

```
function bigsub() {
  var mysum;
  function a() {
   var x;
    function b(sum) {
     var y, z;
     ...
     c(z);
     ...
    } // end of b
    ...
    b(x);
    ...
```

```
   } // end of a
   function c(plums) {
     ... <-----------------------------1
   } // end of c
   var l;
   ...
   a();
   ...
} // end of bigsub
```

3. Show the stack with all activation record instances, including static and dynamic chains, when execution reaches position 1 in the following skeletal program. Assume `bigsub` is at level 1.

```
function bigsub() {
function a(flag) {
  function b() {
    ...
    a(false);
    ...
 } // end of b
 ...
  if (flag)
    b();
  else c();
 ...
} // end of a
 function c() {
   function d() {
     ... <------------------------1
   } // end of d
 ...
   d();
    ...
  } // end of c
  ...
  a(true);
  ...
} // end of bigsub
```

The calling sequence for this program for execution to reach `d` is

`bigsub` calls `a`

`a` calls `b`

`b` calls `a`

`a` calls `c`

`c` calls `d`

4. Show the stack with all activation record instances, including static and dynamic chains, when execution reaches position 1 in the following skeletal program. This program uses the deep-access method to implement dynamic scoping.

```
void fun1() {
  float a;
  . . .
}
void fun2() {
  int b, c;
  . . .
}
void fun3() {
  float d;
  . . . <--------- 1
}
void main() {
  char e, f, g;
   . . .
}
```

The calling sequence for this program for execution to reach `fun3` is

`main` calls `fun2`

`fun2` calls `fun1`

`fun1` calls `fun1`

`fun1` calls `fun3`

5. Assume that the program of Problem 4 is implemented using the shallow-access method using a stack for each variable name. Show the stacks for the time of the execution of `fun3`, assuming execution found its way to that point through the sequence of calls shown in Problem 4.

6. Although local variables in Java methods are dynamically allocated at the beginning of each activation, under what circumstances could the value of a local variable in a particular activation retain the value of the previous activation?

7. It is stated in this chapter that when nonlocal variables are accessed in a dynamic-scoped language using the dynamic chain, variable names must be stored in the activation records with the values. If this were actually done, every nonlocal access would require a sequence of costly string comparisons on names. Design an alternative to these string comparisons that would be faster.

8. Pascal allows gotos with nonlocal targets. How could such statements be handled if static chains were used for nonlocal variable access? *Hint*: Consider the way the correct activation record instance of the static parent of a newly enacted procedure is found (see Section 10.4.2).

9. The static-chain method could be expanded slightly by using two static links in each activation record instance where the second points to the static grandparent activation record instance. How would this approach affect the time required for subprogram linkage and nonlocal references?

10. Design a skeletal program and a calling sequence that results in an activation record instance in which the static and dynamic links point to different activation-recorded instances in the run-time stack.

11. If a compiler uses the static chain approach to implementing blocks, which of the entries in the activation records for subprograms are needed in the activation records for blocks?

12. Examine the subprogram call instructions of three different architectures, including at least one CISC machine and one RISC machine, and write a short comparison of their capabilities. (The design of these instructions usually determines at least part of the compiler writer's design of subprogram linkage.)

PROGRAMMING EXERCISES

1. Write a program that includes two subprograms, one that takes a single parameter and performs some simple operation on that parameter and one that takes 20 parameters and uses all of the parameters, but only for one simple operation. The main program must call these two subprograms a large number of times. Include in the program timing code to output the run time of the calls to each of the two subprograms. Run the program on a RISC machine and on a CISC machine and compare the ratios of the time required by the two subprograms. Based on the results, what can you say about the speed of parameter passing on the two machines?

11 Abstract Data Types and Encapsulation Constructs

In this chapter, we explore programming language constructs that support data abstraction. Among the new ideas of the last 50 years in programming methodologies and programming language design, data abstraction is one of the most profound.

We begin by discussing the general concept of abstraction in programming and programming languages. Data abstraction is then defined and illustrated with an example. This topic is followed by descriptions of the support for data abstraction in C++, Java, C#, and Ruby. To illuminate the similarities and differences in the design of the language facilities that support data abstraction, implementations of the same example data abstraction are given in C++, Java, and Ruby. Next, the capabilities of C++, Java 5.0, and C# 2005 to build parameterized abstract data types are discussed.

All the languages used in this chapter to illustrate the concepts and constructs of abstract data types support object-oriented programming, because virtually all contemporary languages support object-oriented programming and nearly all of those that do not, and yet support abstract data types, have faded into

obscurity.

Constructs that support abstract data types are encapsulations of the data and operations on objects of the type. Encapsulations that contain multiple types are required for the construction of larger programs. These encapsulations and the associated namespace issues are also discussed in this chapter.

Some programming languages support logical, as opposed to physical, encapsulations, which are actually used to encapsulate names. These are discussed in Section 11.7.

11.1 The Concept of Abstraction

An **abstraction** is a view or representation of an entity that includes only the most significant attributes. In a general sense, abstraction allows one to collect instances of entities into groups in which their common attributes need not be considered. For example, suppose we define birds to be creatures with the following attributes: two wings, two legs, a tail, and feathers. Then, if we say a crow is a bird, a description of a crow need not include those attributes. The same is true for robins, sparrows, and yellow-bellied sapsuckers. The common attributes in the descriptions of specific species of birds can be abstracted away, because all species have them. Within a particular species, only the attributes that distinguish that species need be considered. For example, crows have the attributes of being black, being of a particular size, and being noisy. A description of a crow needs to provide those attributes, but not the others that are common to all birds. This results in significant simplification of the descriptions of members of the species. A less abstract view of a species, that of a bird, may be considered when it is necessary to see a higher level of detail, rather than just the special attributes.

In the world of programming languages, abstraction is a weapon against the complexity of programming; its purpose is to simplify the programming process. It is an effective weapon because it allows programmers to focus on essential attributes, while ignoring subordinate attributes.

The two fundamental kinds of abstraction in contemporary programming languages are process abstraction and data abstraction.

The concept of **process abstraction** is among the oldest in programming language design (Plankalkül supported process abstraction in the 1940s). All subprograms are process abstractions because they provide a way for a program to specify a process, without providing the details of how it performs its task (at least in the calling program). For example, when a program needs to sort an array of numeric data of some type, it usually uses a subprogram for the sorting process. At the point where the sorting process is required, a statement such as

```
sortInt(list, listLen)
```

is placed in the program. This call is an abstraction of the actual sorting process, whose algorithm is not specified. The call is independent of the algorithm implemented in the called subprogram.

In the case of the subprogram `sortInt`, the only essential attributes are the name of the array to be sorted, the type of its elements, the array's length, and the fact that the call to `sortInt` will result in the array being sorted. The particular algorithm that `sortInt` implements is an attribute that is not essential to the user. The user needs to see only the name and protocol of the sorting subprogram to be able to use it.

The widespread use of data abstraction necessarily followed that of process abstraction because an integral and essential part of every data abstraction is its operations, which are defined as process abstractions.

11.2 Introduction to Data Abstraction

The evolution of data abstraction began in 1960 with the first version of COBOL, which included the record data structure.1 The C-based languages have structs, which are also records. An abstract data type is a data structure, in the form of a record, but which includes subprograms that manipulate its data.

1. Recall from Chapter 2 that a record is a data structure that stores fields, which have names and can be of different types.

Syntactically, an abstract data type is an enclosure that includes only the data representation of one specific data type and the subprograms that provide the operations for that type. Through access controls, unnecessary details of the type can be hidden from units outside the enclosure that use the type. Program units that use an abstract data type can declare variables of that type, even though the actual representation is hidden from them. An instance of an abstract data type is called an **object**.

One of the motivations for data abstraction is similar to that of process abstraction. It is a weapon against complexity; a means of making large and/or complicated programs more manageable. Other motivations for and advantages of abstract data types are discussed later in this section.

Object-oriented programming, which is described in Chapter 12, is an outgrowth of the use of data abstraction in software development, and data abstraction is one of its fundamental components.

11.2.1 Floating-Point as an Abstract Data Type

The concept of an abstract data type, at least in terms of built-in types, is not a recent development. All built-in data types, even those of Fortran I, are abstract data types, although they are rarely called that. For example, consider a floating-point data type. Most programming languages include at least one of these. A floating-point type provides the means to create variables to store floating-point data and also provides a set of arithmetic operations for manipulating objects of the type.

Floating-point types in high-level languages employ a key concept in data abstraction: information hiding. The actual format of the floating-point data value in a memory cell is hidden from the user, and the only operations available are those provided by the language. The user is not allowed to create new operations on data of the type, except those that can be constructed using the built-in operations. The user cannot directly manipulate the parts of the actual representation of values because that representation is hidden. It is this feature that allows program portability between implementations of a particular language, even though the implementations may use different representations for particular data types. For example, before the IEEE 754 standard floating-point representations appeared in the mid-1980s, there were several different representations being used by different computer architectures. However, this variation did not prevent programs that used floating-point types from being portable among the various architectures.

11.2.2 User-Defined Abstract Data Types

A user-defined abstract data type should provide the same characteristics as those of language-defined types, such as a floating-point type: (1) a type definition that allows program units to declare variables of the type but hides the representation of objects of the type; and (2) a set of operations for manipulating objects of the type.

We now formally define an abstract data type in the context of user-defined types. An **abstract data type** is a data type that satisfies the following

conditions:

- The representation of objects of the type is hidden from the program units that use the type, so the only direct operations possible on those objects are those provided in the type's definition.

- The declarations of the type and the protocols of the operations on objects of the type, which provide the type's interface, are contained in a single syntactic unit. The type's interface does not depend on the representation of the objects or the implementation of the operations. Also, other program units are allowed to create variables of the defined type.

There are several benefits of information hiding. One of these is increased reliability. Program units that use a specific abstract data type are called **clients** of that type. Clients cannot manipulate the underlying representations of objects directly, either intentionally or by accident, thus increasing the integrity of such objects. Objects can be changed only through the provided operations.

Another benefit of information hiding is it reduces the range of code and number of variables of which a programmer must be aware when writing or reading a part of the program. The value of a particular variable can be changed only by code in a restricted range, making the code easier to understand and making it less challenging to find sources of incorrect changes.

Information hiding also makes name conflicts less likely, because the scopes of variables is smaller.

Finally, consider the following advantage of information hiding: Suppose that the original implementation of the stack abstraction uses a linked list representation. At a later time, because of memory management problems with that representation, the stack abstraction is changed to use a contiguous representation (one that implements a stack in an array). Because data abstraction was used, this change can be made in the code that defines the stack type, but no changes will be required in any of the clients of the stack abstraction. Of course, a change in protocol of any of the operations would

require changes in the clients.

Although the definition of an abstract data type specifies that data members of objects must be hidden from clients, many situations arise in which clients need to access these data members. The common solution is to provide accessor methods, sometimes called **getters** and **setters**, that allow clients indirect access to the so-called hidden data—a better solution than simply making the data public, which would provide direct access. There are three reasons why accessors are better:

1. Read-only access can be provided by having a getter method but no corresponding setter method.

2. Constraints can be included in setters. For example, if the data value should be restricted to a particular range, the setter can enforce that.

3. The actual implementation of the data member can be changed without affecting the clients if getters and setters are the only access.

Both specifying data in an abstract data type to be public and providing accessor methods for that data are violations of the principles of abstract data types. Some believe these are simply loopholes that make an imperfect design usable. As we will see in Section 11.4.4.2, Ruby disallows making instance data public. However, Ruby also makes it very easy to create accessor functions. It is a challenge for developers to design abstract data types in which all of the data is actually hidden.

The primary advantage of packaging the declarations of the type and its operations in a single syntactic unit is that it provides a method of organizing a program into logical units that can be compiled separately. In some cases, the implementation is included with the type declaration; in other cases, it is in a separate syntactic unit. The advantage of having the implementation of the type and its operations in different syntactic units is that it increases the program's modularity and it is a clear separation of design and implementation. If both the declarations and the definitions of types and operations are in the same syntactic unit, there must be some means of hiding from client program units the parts of the unit that specify the definitions.

11.2.3 An Example

A stack is a widely applicable data structure that stores some number of data elements and only allows access to the data element at one of its ends, the top. Suppose an abstract data type is to be constructed for a stack that has the following abstract operations:

create(stack)	Creates and possibly initializes a stack object
destroy(stack)	Deallocates the storage for the stack
empty(stack)	A predicate (or Boolean) function that returns true if the specified stack is empty and false otherwise
push(stack, element)	Pushes the specified element on the specified stack
pop(stack)	Removes the top element from the specified stack
top(stack)	Returns a copy of the top element from the specified stack

Note that some implementations of abstract data types do not require the create and destroy operations. For example, simply defining a variable to be of an abstract data type may implicitly create the underlying data structure and initialize it. The storage for such a variable may be implicitly deallocated at the end of the variable's scope.

A client of the stack type could have a code sequence such as the following:

```
. . .
create(stk1);
push(stk1, color1);
push(stk1, color2);
temp = top(stk1);
. . .
```

11.3 Design Issues for Abstract Data Types

A facility for defining abstract data types in a language must provide a syntactic unit that encloses the declaration of the type and the prototypes of the subprograms that implement the operations on objects of the type. It must be possible to make these visible to clients of the abstraction. This allows clients to declare variables of the abstract type and manipulate their values. Although the type name must have external visibility, the type representation must be hidden. The type representation and the definitions of the subprograms that implement the operations may appear inside or outside this syntactic unit.

Few, if any, general built-in operations should be provided for objects of abstract data types, other than those provided with the type definition. There simply are not many operations that apply to a broad range of abstract data types. Among these are assignment and comparisons for equality and inequality. If the language does not allow users to overload assignment, the assignment operation must be included in the abstraction. Comparisons for equality and inequality should be predefined in the abstraction in some cases but not in others. For example, if the type is implemented as a pointer, equality may mean pointer equality, but the designer may want it to mean equality of the structures referenced by the pointers.

Some operations are required by many abstract data types, but because they are not universal, they often must be provided by the designer of the type. Among these are iterators, accessors, constructors, and destructors. Iterators were discussed in Chapter 8. Accessors provide a form of access to data that is hidden from direct access by clients. Constructors are used to initialize parts of newly created objects. Destructors are often used to reclaim heap storage that may be used by parts of abstract data type objects in languages that do not do implicit storage reclamation.

As stated earlier, the enclosure for an abstract data type defines a single data

type and its operations. Many contemporary languages, including C++, Java, and C#, directly support abstract data types.

The first design issue is whether abstract data types can be parameterized. For example, if the language supports parameterized abstract data types, one could design an abstract data type for some structure that could store elements of any type. Parameterized abstract data types are discussed in Section 11.5. The second design issue is what access controls are provided and how such controls are specified. Finally, the language designer must decide whether the specification of the type is physically separate from its implementation (or whether that is a developer choice).

11.4 Language Examples

The concept of data abstraction had its origins in SIMULA 67, although that language did not provide complete support for abstract data types, because it did not include a way to hide implementation details. In this section, we describe the support for data abstraction provided by C++, Java, C#, and Ruby.

11.4.1 Abstract Data Types in C++

C++, which was first released in 1985, was created by adding features to C. The first important additions were those to support object-oriented programming. Because one of the primary components of object-oriented programming is abstract data types, C++ obviously is required to support them.

C++ provides two constructs that are very similar to each other, the class and the struct, which directly support abstract data types. Because structs are most commonly used when only data is included, we do not discuss them further here.

interview

C++: Its Birth, Its Ubiquitousness, and Common Criticisms

BJARNE STROUSTRUP

Bjarne Stroustrup is the designer and original implementer of C++ and the author of A Tour of C++, Programming—Principles and Practice using C++, The C++ Programming Language, The Design and Evolution of C++, and many other publications. His research interests include distributed systems, design, programming techniques, software development tools, and programming languages. He is actively involved in the ANSI/ISO standardization of C++. Dr. Stroustrup is a Managing Director in the technology division of Morgan Stanley in New York City, a Visiting Professor in Computer Science at Columbia University, and a Distinguished Research Professor in Computer Science at Texas A&M University. He is a member of the National Academy of Engineering, an ACM Fellow, and an IEEE fellow. In 1993, Stroustrup received the ACM Grace Murray Hopper Award “for his early work laying the foundations for the C++ programming language. Based on the foundations and Dr. Stroustrup’s continuing efforts, C++ has become one of the most influential programming languages in the history of computing.”

(year of interview: 2002)

A BRIEF HISTORY OF YOU AND COMPUTING

What were you working on, and where, before you joined Bell Labs in the early 1980s? At Bell Labs, I was doing research in the general area of distributed systems. I joined in 1979. Before that, I was finishing my Ph.D. in that field in Cambridge University.

Did you immediately start on "C with Classes" (which would later become C ++)? I worked on a few projects related to distributed computing before starting on C with Classes and during the development of that and of C++. For example, I was trying to find a way to distribute the UNIX kernel across several computers and helped a lot of projects build simulators.

Was it an interest in mathematics that got you into this profession? I signed up for a degree in "mathematics with computer science" and my master's degree is officially a math degree. I—wrongly—thought that computing was some kind of applied math. I did a couple of years of math and rate myself a poor mathematician, but that's still much better than not knowing math. At the time I signed up, I had never even seen a computer. What I love about computing is the programming rather than the more mathematical fields.

DISSECTING A SUCCESSFUL LANGUAGE

I'd like to work backward, listing some items I think make C++ ubiquitous, and get your reaction. It's "open source," nonproprietary, and standardized by ANSI/ISO. The ISO C++ standard is important. There are many independently developed and evolving C++ implementations. Without a standard for them to adhere to and a standards process to help coordinate the evolution of C++, a chaos of dialects would erupt.

It is also important that there are both open-source and commercial implementations available. In addition, for many users, it is crucial that the standard provides a measure of protection from manipulation by implementation providers.

The ISO standards process is open and democratic. The C++ committee rarely meets with fewer than 50 people present and typically more than eight nations are represented at each meeting. It is not just a vendors' forum.

It's ideal for systems programming (which, at the time C++ was born, was the largest sector of the market developing code).

Yes, C++ is a strong contender for any systems-programming project. It is also effective for embedded systems programming, which is currently the fastest-growing sector. Yet another growth area for C++ is high-performance numeric/engineering/scientific programming.

Its object-oriented nature and inclusion of classes/libraries make programming more efficient and transparent. C++ is a multiparadigm programming language. That is, it supports several fundamental styles of programming (including object-oriented programming) and combinations of those styles. When used well, this leads to cleaner, more flexible, and more efficient libraries than can be provided using just one paradigm. The C++ standard library containers and algorithms, which is basically a generic programming framework, is an example. When used together with (object-oriented) class hierarchies, the result is an unsurpassed combination of type safety, efficiency, and flexibility.

Its incubation in the AT&T development environment AT&T Bell Labs provided an environment that was crucial for C++'s development. The labs were an exceptionally rich source of challenging problems and a uniquely supportive environment for practical research. C++ emerged from the same research lab as C did and benefited from the same intellectual tradition, experience, and exceptional people. Throughout, AT&T supported the standardization of C++. However, C++ was not the beneficiary of a massive marketing campaign, like many modern languages. That's simply not the way the labs work.

Did I miss anything on your top list? Undoubtedly.

Now, let me paraphrase from the C++ critiques and get your reactions: It's huge/unwieldy. The "hello world" problem is 10 times larger in C++ than in C. C++ is certainly not a small language, but then few modern languages are. If a language is small, you tend to need huge libraries to get work done and often have to rely on conventions and extensions. I prefer to have key parts of the inevitable complexity in the language where it can be seen, taught, and effectively standardized rather than hidden elsewhere in a system. For most purposes, I don't consider C++ unwieldy. The C++ "hello world" program isn't larger than its C equivalent on my machine, and it shouldn't be on yours.

In fact, the object code for the C++ version of the "hello world" program is smaller than the C version on my machine. There is no language reason why the one version should be larger than the other. It is all an issue of how the implementor organized the libraries. If one version is significantly larger than the other, report the problem to the implementor of the larger version.

It's tougher to program in C++ (compared with C). (Something the critics say.) Even you once admitted it, saying something about shooting yourself in the foot with C versus C ++. Yes, I did say something along the lines of "C makes it easy to shoot yourself in the foot; C++ makes it harder, but when you do, C++ blows your whole leg off." What people tend to miss is that what I said about C++ is to a varying extent true for all powerful languages. As you protect people from simple dangers, they get themselves into new and less obvious problems. Someone who avoids the simple problems may simply be heading for a not-so-simple one. One problem with very supporting and protective environments is that the hard problems may be discovered too late or be too hard to remedy once discovered. Also, a rare problem is harder to find than a frequent one because you don't suspect it.

It's appropriate for embedded systems of today but not for the Internet software of today. C++ is suitable for embedded systems today. It is also suitable—and widely used—for "Internet software" today. For example, have a look at my "C++ applications" Web page. You'll notice that some of the major Web service providers, such as Amazon, Adobe, Google, Quicken, and Microsoft, critically rely on C++. Gaming is a related area in which you find

heavy C++ use.

Did I miss another one that you get a lot? Sure.

C++ classes are types. A C++ program unit that declares an instance of a class can also access any of the public entities in that class, but only through an instance of the class.

11.4.1.1 Encapsulation

The data defined in a C++ class are called **data members**; the functions (methods) defined in a class are called **member functions**. Data members and member functions appear in two categories: class and instance. Class members are associated with the class; instance members are associated with the instances of the class. In this chapter, only the instance members of a class are discussed. All of the instances of a class share a single set of member functions, but each instance has its own set of the class's data members. Class instances can be static, stack dynamic, or heap dynamic. If static or stack dynamic, they are referenced directly with value variables. If heap dynamic, they are referenced through pointers. Stack dynamic instances of classes are always created by the elaboration of an object declaration. Furthermore, the lifetime of such a class instance ends when the end of the scope of its declaration is reached. Heap dynamic class instances are created with the `new` operator and destroyed with the `delete` operator. Both stack- and heap-dynamic classes can have pointer data members that reference heap dynamic data, so that even though a class instance is stack dynamic, it can include data members that reference heap dynamic data.

A member function of a class can be defined in two distinct ways: The complete definition can appear in the class, or only in its header. When both the header and the body of a member function appear in the class definition, the member function is implicitly inlined. Recall that this means that its code is placed in the caller's code, rather than requiring the usual call and return linkage. If only the header of a member function appears in the class definition, its complete definition appears outside the class and is separately compiled. The rationale for allowing member functions to be inlined was to

save function call overhead in real-time applications, in which run-time efficiency is of utmost importance. The downside of inlining member functions is that it clutters the class definition interface, resulting in a reduction in readability.

Placing member function definitions outside the class definition separates specification from implementation, a common goal of modern programming.

11.4.1.2 Information Hiding

A C++ class can contain both hidden and visible entities (meaning they are either hidden from or visible to clients of the class). Entities that are to be hidden are placed in a **`private`** clause, and visible, or public, entities appear in a **`public`** clause. The **`public`** clause therefore describes the interface to class instances. There is also a third category of visibility, **`protected`**, which makes a member visible to subclasses, but not to clients.

11.4.1.3 Constructors and Destructors

C++ allows the user to include **constructor** functions in class definitions, which are used to initialize the data members of newly created objects. A constructor may also allocate the heap-dynamic data that are referenced by the pointer members of the new object. Constructors are implicitly called when an object of the class type is created. A constructor has the same name as the class whose objects it initializes. Constructors can be overloaded, but of course each constructor of a class must have a unique parameter profile.

A C++ class can also include a function called a **destructor**, which is implicitly called when the lifetime of an instance of the class ends. As stated earlier, stack-dynamic class instances can contain pointer members that reference heap-dynamic data. The destructor function for such an instance can include a **`delete`** operator on the pointer members to deallocate the heap

space they reference. Destructors are often used as a debugging aid, in which case they display or print the values of some or all of the object's data members before those members are deallocated. The name of a destructor is the class's name, preceded by a tilde (~).

Neither constructors nor destructors have return types, and neither use **`return`** statements. Both constructors and destructors can be explicitly called.

11.4.1.4 An Example

Our example of a C++ abstract data type is a stack:

```
#include <iostream.h>
class Stack {
  private:  //** These members are visible only to other
            //** members and friends (see Section 11.6.4)
    int *stackPtr;
    int maxLen;
    int topSub;
  public:  //** These members are visible to clients
    Stack() { //** A constructor
      stackPtr = new int [100];
      maxLen = 99;
      topSub = -1;
    }
    ~Stack() {delete  [] stackPtr;};  //** A destructor
    void push(int number) {
      if (topSub == maxLen)
        cerr << "Error in push--stack is full\n";
      else stackPtr[++topSub] = number;
    }
    void pop() {
      if (empty())
        cerr << "Error in pop--stack is empty\n";
      else topSub--;
    }
    int top() {
       if  (empty())
         cerr << "Error in top--stack is empty\n";
       else
         return  (stackPtr[topSub]);
    }
    int  empty() {return  (topSub == -1);}
```

```
}
```

We discuss only a few aspects of this class definition, because it is not necessary to understand all of the details of the code. Objects of the `Stack` class are stack dynamic but include a pointer that references heap-dynamic data. The `Stack` class has three data members—`stackPtr`, `maxLen`, and `topSub`—all of which are private. `stackPtr` is used to reference the heap-dynamic data, which is the array that implements the stack. The class also has four public member functions—`push`, `pop`, `top`, and `empty`—as well as a constructor and a destructor. All of the member function definitions are included in this class, although they could have been externally defined. Because the bodies of the member functions are included, they are all implicitly inlined. The constructor uses the **`new`** operator to allocate an array of 100 **`int`** elements from the heap. It also initializes `maxLen` and `topSub`.

The following is an example program that uses the `Stack` abstract data type:

```
void main() {
  int topOne;
  Stack stk;  //** Create an instance of the Stack class
  stk.push(42);
  stk.push(17);
  topOne = stk.top();
  stk.pop();
  . . .
}
```

Following is a definition of the `Stack` class with only prototypes of the member functions. This code is stored in a header file with the `.h` file name extension. The definitions of the member functions follow the class definition. These use the scope resolution operator, `::`, to indicate the class to which they belong. These definitions are stored in a code file with the file name extension `.cpp`.

```
// Stack.h - the header file for the Stack class
#include <iostream.h>
class Stack {
  private:  //** These members are visible only to other
            //** members and friends (see Section 11.6.3)
    int *stackPtr;
    int maxLen;
    int topSub;
```

```
  public:    //** These members are visible to clients
    Stack();  //** A constructor
    ~Stack();  //** A destructor
    void push(int);
    void pop();
    int top();
    int empty();
}
// Stack.cpp - the implementation file for the Stack class
#include <iostream.h>
#include "Stack.h"
using std::cout;
Stack::Stack() {  //** A constructor
  stackPtr =  new int  [100];
  maxLen = 99;
  topSub = -1;
}
Stack::~Stack() {delete  [] stackPtr;};  //** A destructor
void Stack::push(int  number) {
  if (topSub == maxLen)
    cerr << "Error in push--stack is full\n";
  else  stackPtr[++topSub] = number;
}
void Stack::pop() {
  if (topSub == -1)
    cerr << "Error in pop--stack is empty\n";
  else  topSub--;
}
int top() {
      if  (topSub == -1)
        cerr << "Error in top--stack is empty\n";
      else
        return  (stackPtr[topSub]);
    }
int Stack::empty() {return  (topSub == -1);}
```

11.4.2 Abstract Data Types in Java

Java support for abstract data types is similar to that of C++. There are, however, a few important differences. All objects are allocated from the heap and accessed through reference variables. Methods in Java must be defined

completely in a class. A method body must appear with its corresponding method header.2 Therefore, a Java abstract data type is both declared and defined in a single syntactic unit. A Java compiler can inline any method that is not overridden. Definitions are hidden from clients by declaring them to be private.

2. Java interfaces are an exception to this—an interface has method headers but cannot include their bodies.

One important advantage of Java's classes over the classes of C++ is that it uses implicit garbage collection of all objects. This allows the programmer to ignore the issue of deallocation of objects and the clutter of deallocation code in the implementations of abstract data types.

Rather than having private and public clauses in its class definitions, in Java access modifiers can be attached to method and variable definitions. If an instance variable or method does not have an access modifier, it has package access, which is discussed in Section 11.7.2.

11.4.2.1 An Example

The following is a Java class definition for our stack example:

```
class StackClass {
  private int [] stackRef;
  private int maxLen,
              topIndex;
  public StackClass() {  // A constructor
    stackRef = new int [100];
    maxLen = 99;
    topIndex = -1;
  }
  public void push(int number) {
    if (topIndex == maxLen)
      System.out.println("Error in push–stack is full");
    else stackRef[++topIndex] = number;
  }
  public void pop() {
    if (empty())
      System.out.println("Error in pop–stack is empty");
```

```
    else --topIndex;
  }
  public int top() {
    if (empty()) {
      System.out.println("Error in top–stack is empty");
      return  9999;
    }
    else
      return (stackRef[topIndex]);
  }
  public boolean empty() {return (topIndex == -1);}
}
```

An example class that uses `StackClass` follows:

```
public class TstStack {
  public static void main(String[] args) {
    StackClass myStack = new StackClass();
    myStack.push(42);
    myStack.push(29);
    System.out.println("29 is: " + myStack.top());
    myStack.pop();
    System.out.println("42 is: " + myStack.top());
    myStack.pop();
    myStack.pop(); // Produces an error message
  }
}
```

One obvious difference between the Java and the C++ implementations of the stack is the lack of a destructor in the Java version, obviated by Java's implicit garbage collection.3

3. In Java, the **`finalize`** method serves as a kind of destructor.

11.4.2.2 Evaluation

Although different in some primarily cosmetic ways, Java's support for abstract data types is similar to that of C++. Java clearly provides for what is necessary to design abstract data types.

11.4.3 Abstract Data Types in C#

Recall that C# is based on both C++ and Java and that it also includes some new constructs. Like Java, all C# class instances are heap dynamic. Default constructors, which provide initial values for instance data, are predefined for all classes. These constructors provide typical initial values, such as `0` for **`int`** types and **`false`** for **`boolean`** types. A user can furnish one or more constructors for any class he or she defines. Such constructors can assign initial values to some or all of the instance data of the class. Any instance variable that is not initialized in a user-defined constructor is assigned a value by the default constructor.

Although C# allows destructors to be defined, because it uses garbage collection for most of its heap objects, destructors are rarely used.

11.4.3.1 Encapsulation

C++ includes both classes and structs, which are nearly identical constructs. The only difference is that the default access modifier for class is **`private`**, whereas for structs it is **`public`**. C# also has structs, but they are very different from those of C++. In C#, structs are, in a sense, lightweight classes. They can have constructors, properties, methods, and data fields and can implement interfaces but do not support inheritance. One other important difference between structs and classes in C# is that structs are value types, as opposed to reference types. They are allocated on the run-time stack, rather than the heap. If they are passed as parameters, like other value types, by default they are passed by value. All C# value types, including all of its primitive types, are actually structs. Structs can be created by declaring them, like other predefined value types, such as **`int`** or **`float`**. They can also be created with the **`new`** operator, which calls a constructor to initialize them.

Structs are used in C# primarily to implement relatively small simple types that need never be base types for inheritance. They are also used when it is convenient for the objects of the type to be stack as opposed to heap allocated.

11.4.3.2 Information Hiding

C# uses the **`private`** and **`protected`** access modifiers exactly as they are used in Java.

C# provides properties, which it inherited from Delphi, as a way of implementing getters and setters without requiring explicit method calls by the client. Properties provide implicit access to specific private instance data. For example, consider the following simple class and client code:

```
public class  Weather {
  public int  DegreeDays {  //** DegreeDays is a property
    get {
       return  degreeDays;
    }
     set {
       if(value < 0 || value > 30)
         Console.WriteLine(
              "Value is out of range: {0}",  value);
       else
         degreeDays = value;
    }
  }
  private int degreeDays;
   . . .
  }
. . .
Weather w =  new Weather();
int  degreeDaysToday, oldDegreeDays;
. . .
w.DegreeDays = degreeDaysToday;
. . .
oldDegreeDays = w.DegreeDays;
```

In the class `Weather`, the property `DegreeDays` is defined. This property provides a getter method and a setter method for access to the private data member, `degreeDays`. In the client code following the class definition, `degreeDays` is treated as if it were a public-member variable, although access to it is available through the property only. Notice the use of the implicit variable **`value`** in the setter method. This is the mechanism by which the new value of the property is referenced.

The stack example is not shown here in C#. The only difference between the Java version in Section 11.4.2.1 and the C# version is the output method calls and the use of **bool** instead of **boolean** for the return type of the empty method.

11.4.4 Abstract Data Types in Ruby

Ruby provides support for abstract data types through its classes. In terms of capabilities, Ruby classes are similar to those in C++ and Java.

11.4.4.1 Encapsulation

In Ruby, a class is defined in a compound statement opened with the **class** reserved word and closed with **end**. The names of instance variables have a special syntactic form, they must begin with at signs (@). Instance methods have the same syntax as functions in Ruby: They begin with the **def** reserved word and end with **end**. Class methods are distinguished from instance methods by having the class name appended to the beginning of their names with a period separator. For example, in a class named Stack, a class method's name would begin with Stack. Constructors in Ruby are named initialize. Because the constructor cannot be overloaded, there only can be one per class.

Classes in Ruby are dynamic in the sense that members can be added at any time. This is done by simply including additional class definitions that specify the new members. Moreover, even predefined classes of the language, such as String, can be extended. For example, consider the following class definition:

```
class myClass
  def meth1
    . . .
  end
```

```
end
```

This class could be extended by adding a second method, `meth2`, with a second class definition:

```
class myClass
  def meth2
    . . .
  end
end
```

Methods can also be removed from a class. This is done by providing another class definition in which the method to be removed is sent to the method `remove_method` as a parameter. The dynamic classes of Ruby is another example of a language designer trading readability (and as a consequence, reliability) for flexibility. Allowing dynamic changes to classes clearly adds flexibility to the language, while harming readability. To determine the behavior of a class at a particular point in a program, one must find all of its definitions in the program and consider all of them.

11.4.4.2 Information Hiding

Access control for methods in Ruby is dynamic, so access violations are detected only during execution. The default method access is public, but it can also be protected or private. There are two ways to specify the access control, both of which use functions with the same names as the access levels, **`private`** and **`public`**. One way is to call the appropriate function without parameters. This resets the default access for subsequently defined methods in the class. For example,

```
class MyClass
  def meth1
  . . .
  end
  . . .
private
  def meth7
  . . .
  end
  . . .
```

```
end   # of class MyClass
```

The alternative is to call the access control functions with the names of the specific methods as parameters. For example, the following is semantically equivalent to the previous class definition:

```
class MyClass
  def meth1
  . . .
  end
  . . .
  def meth7
  . . .
  end
  private :meth7, . . .
   end # of class MyClass
```

In Ruby, all data members of a class are private, and that cannot be changed. So, data members can be accessed only by the methods of the class, some of which may be accessor methods. In Ruby, instance data that are accessible through accessor methods are called **attributes**.

For an instance variable named `@sum`, the getter and setter methods would be as follows:

```
def sum
  @sum
end
def sum=(new_sum)
  @sum = new_sum
end
```

Notice that getters are given the name of the instance variable minus the `@`. The names of setter methods are the same as those of the corresponding getters, except they have an equal sign (`=`) attached.

Getters and setters can be implicitly generated by the Ruby system by including calls to `attr_reader` and `attr_writer`, respectively, in the class definition. The parameters to these are the symbols of the attribute’s names, as is illustrated in the following:

```
attr_reader :sum, :total
```

```
attr_writer :sum
```

11.4.4.3 An Example

Following is the stack example written in Ruby:

```
# Stack.rb - defines and tests a stack of maximum length
#             100, implemented in an array
class  StackClass
# Constructor
  def initialize
    @stackRef = Array.new(100)
    @maxLen = 100
    @topIndex = -1
  end
# push method
   def push(number)
     if @topIndex == @maxLen
       puts "Error in push - stack is full"
     else
       @topIndex = @topIndex + 1
       @stackRef[@topIndex] = number
      end
      end
# pop method
  def pop
     if empty
       puts "Error in pop - stack is empty"
     else
       @topIndex = @topIndex - 1
     end
   end
# top method
   def top
     if empty
       puts "Error in top - stack is empty"
     else
       @stackRef[@topIndex]
     end
   end
# empty method
  def empty
    @topIndex == -1
  end
```

```
end  # of Stack class
# Test code for StackClass
myStack = StackClass.new
myStack.push(42)
myStack.push(29)
puts "Top element is (should be 29): #{myStack.top}"
myStack.pop
puts "Top element is (should be 42): #{myStack.top}"
myStack.pop
# The following pop should produce an
# error message - stack is empty
myStack.pop
```

Recall that the notation `#{variable}` converts the value of the variable to a string, which is then inserted into the string in which it appears. This class defines a stack structure that can store objects of any type.

11.4.4.4 Evaluation

Recall that in Ruby, everything is an object and arrays are actually arrays of references to objects. That clearly makes this stack more flexible than the similar examples in C++ and Java. Furthermore, simply by passing the desired maximum length to the constructor, objects of this class could have any given maximum length. Of course, because arrays in Ruby have dynamic length, the class could be modified to implement stack objects that are not restricted to any length, except that imposed by the machine’s memory capacity. Because the names of class and instance variables have different forms, Ruby has a slight readability advantage over the other languages discussed in this section.

11.5 Parameterized Abstract Data Types

It is often convenient to be able to parameterize abstract data types. For example, we should be able to design a stack abstract data type that can store any scalar type elements rather than be required to write a separate stack abstraction for every different scalar type. Note that this is only an issue for static typed languages. In a dynamic typed language like Ruby, any stack implicitly can store any type elements. In fact, different elements of the stack could be of different types. In the following three subsections, the capabilities of C++, Java 5.0, and C# 2005 to construct parameterized abstract data types are discussed.

11.5.1 C++

To make the example C++ stack class of Section 11.4.1 generic in the stack size, only the constructor function needs to be changed, as in the following:

```
Stack(int size) {
  stackPtr = new int  [size];
  maxLen = size - 1;
  topSub = -1;
}
```

The declaration for a stack object now may appear as follows:

```
Stack stk(150);
```

The class definition for `Stack` can include both constructors, so users can use the default-size stack or specify some other size.

The element type of the stack can be made generic by making the class a templated class. Then, the element type can be a template parameter. The definition of the templated class for a stack type is as follows:

```
#include <iostream.h>
template <typename Type>  // Type is the template parameter
class Stack {
  private:
    Type *stackPtr;
    int maxLen;
    int topSub;
  public:
// A constructor for 100 element stacks
    Stack() {
      stackPtr = new Type [100];
      maxLen = 99;
      topSub = -1;
    }
// A constructor for a given number of elements
    Stack(int size) {
      stackPtr = new Type [size];
      maxLen = size - 1;
      topSub = -1;
    }
    ~Stack() {delete  stackPtr;};  // A destructor
    void push(Type number) {
      if (topSub == maxLen)
        cout << "Error in push–stack is full\n";
      else  stackPtr[++ topSub] = number;
    }
    void pop() {
      if (empty())
        cout << "Error in pop–stack is empty\n";
      else  topSub --;
    }
    Type top() {
      if (empty())
       cerr << "Error in top--stack is empty\n";
      else
        return  (stackPtr[topSub]);
    }
    int  empty() {return  (topSub == -1);}
}
```

C++ templated classes are instantiated to become typed classes at compile time. For example, an instance of the templated `Stack` class, as well as an instance of the typed class, can be created with the following declaration:

```
Stack<int> myIntStack;
```

However, if an instance of the templated `Stack` class has already been created for the **`int`** type, the typed class need not be created.

11.5.2 Java 5.0

Java 5.0 supports a form of parameterized abstract data types in which the generic parameters must be classes. Recall that these were briefly discussed in Chapter 9.

The most common generic types are collection types, such as `LinkedList` and `ArrayList`, which were in the Java class library before support for generics was added. The original collection types stored `Object` class instances, so they could store any objects (but not primitive types). Therefore, the collection types have always been able to store multiple types (as long as they are classes). There were three issues with this: First, every time an object was removed from the collection, it had to be cast to the appropriate type. Second, there was no error checking when elements were added to the collection. This meant that once the collection was created, objects of any class could be added to the collection, even if the collection was meant to store only `Integer` objects. Third, the collection types could not store primitive types. So, to store **`int`** values in an `ArrayList`, the value first had to be put in an `Integer` class instance. For example, consider the following code:

```
//* Create an ArrayList object
ArrayList myArray = new ArrayList();
//* Create an element
myArray.add(0, new Integer(47));
//* Get first object
Integer myInt = (Integer)myArray.get(0);
```

In Java 5.0, the collection classes, the most commonly used of which is `ArrayList`, became a generic class. Such classes are instantiated by calling **`new`** on the class constructor and passing it the generic parameter in pointed - brackets. For example, the `ArrayList` class can be instantiated to store `Integer` objects with the following statement:

```
ArrayList <Integer> myArray = new ArrayList <Integer>();
```

This new class overcomes two of the problems with pre-Java 5.0 collections. Only `Integer` objects can be put into the `myArray` collection. Furthermore, there is no need to cast an object being removed from the collection.

Java 5.0 also includes generic collections for linked-lists, queues, and sets. Users also can define generic classes in Java 5.0. For example, we could have the following:

```
public class MyClass<T> {
  . . .
}
```

This class could be instantiated with the following:

```
MyClass<String> myString;
```

There are some drawbacks to these user-defined generic classes. For one thing, they cannot store primitives. Second, the elements cannot be indexed. Elements must be added to user-defined generic collections with the `add` method. Next, we implement the generic stack example using an `ArrayList`. Note that the last element of an `ArrayList` is found using the `size` method, which returns the number of elements in the structure. Elements are deleted from the structure with the `remove` method. Following is the generic class:

```
import  java.util.*;
public class  Stack2<T> {
  private ArrayList<T> stackRef;
  private int maxLen;
  public Stack2() { // A constructor
    stackRef = new ArrayList<T> ();
    maxLen = 99;
  }
  public void push(T newValue) {
    if (stackRef.size() == maxLen)
      System.out.println("Error in push–stack is full");
    else
      stackRef.add(newValue);
  }
  public void pop() {
    if (empty())
      System.out.println("Error in pop–stack is empty");
    else
     stackRef.remove(stackRef.size() - 1);
```

```
  }
  public T top() {
    if empty()) {
      System.out.println("Error in top–stack is empty");
      return null;  }
    else
      return (stackRef.get(stackRef.size() - 1));
  }
  public boolean empty() {return (stackRef.isEmpty());}
```

This class could be instantiated for the `String` type with the following:

```
Stack2<String> myStack = new Stack2<String>();
```

Recall from Chapter 9, that Java 5.0 supports wildcard classes. For example, `Collection<?>` is a wildcard class for all collection classes. This allows a method to be written that can accept any collection type as a parameter. Because a collection can itself be generic, the `Collection<?>` class is in a sense a generic of a generic class.

Some care must be taken with objects of the wildcard type. For example, because the components of a particular object of this type have a type, other type objects cannot be added to the collection. For example, consider

```
Collection<?> c = new ArrayList<String>();
```

It would be illegal to use the `add` method to put something into this collection unless its type were `String`.

A generic class can easily be defined in Java 5.0 that will work only for a restricted set of types. For example, a class can declare a variable of the generic type and call a method such as `compareTo` through that variable. If the class is instantiated for a type that does not include a `compareTo` method, the class cannot be used. To prevent a generic class from being instantiated for a type that does not support `compareTo`, it could be defined with the following generic parameter:

```
<T extends Comparable>
```

`Comparable` is the interface in which `compareTo` is declared. If this generic type is used on a class definition, the class cannot be instantiated for any type

that does not implement `Comparable`. The choice of the reserved word **`extends`** seems odd here, but its use is related to the concept of a subtype. Apparently, the designers of Java did not want to add another more connotative reserved word to the language.

11.5.3 C# 2005

As was the case with Java, the first version of C# defined collection classes that stored objects of any class. These were `ArrayList`, `Stack`, and `Queue`. These classes had the same problems as the collection classes of pre-Java 5.0.

Generic classes were added to C# in its 2005 version. The five predefined generic collections are `Array`, `List`, `Stack`, `Queue`, and `Dictionary` (the `Dictionary` class implements hashes). Exactly as in Java 5.0, these classes eliminate the problems of allowing mixed types in collections and requiring casts when objects are removed from the collections.

As with Java 5.0, users can define generic classes in C# 2005. One capability of the user-defined C# generic collections is that any of them can be defined to allow its elements to be indexed (accessed through subscripting). Although the indexes are usually integers, an alternative is to use strings as indexes.

One capability that Java 5.0 provides that C# 2005 does not is wildcard classes.

11.6 Encapsulation Constructs

The first five sections of this chapter discussed abstract data types, which are minimal encapsulations. This section describes the multiple-type encapsulations that are needed for larger programs.

11.6.1 Introduction

When the size of a program reaches beyond a few thousand lines, two practical problems become evident. From the programmer's point of view, having such a program appear as a single collection of subprograms or abstract data type definitions does not impose an adequate level of organization on the program to keep it intellectually manageable. The second practical problem for larger programs is recompilation. For relatively small programs, recompiling the whole program after each modification is not costly. But for large programs, the cost of recompilation is significant. So, there is an obvious need to find ways to avoid recompilation of the parts of a program that are not affected by a change. The obvious solution to both of these problems is to organize programs into collections of logically related code and data, each of which can be compiled without recompilation of the rest of the program. An **encapsulation** is such a collection.

Encapsulations are often placed in libraries and made available for reuse in programs other than those for which they were written. People have been writing programs with more than a few thousand lines for at least the last 50 years, so techniques for providing encapsulations have been evolving for some time.

In languages that allow nested subprograms, programs can be organized by nesting subprogram definitions inside the logically larger subprograms that use them. This can be done in Python and Ruby. As discussed in Chapter 5, however, this method of organizing programs, which uses static scoping, is far from ideal. Therefore, even in languages that allow nested subprograms,

they are not used as a primary organizing encapsulation construct.

11.6.2 Encapsulation in C

C does not provide complete support for abstract data types, although both abstract data types and multiple-type encapsulations can be simulated.

In C, a collection of related functions and data definitions can be placed in a file, which can be independently compiled. Such a file, which acts as a library, has an implementation of its entities. The interface to such a file, including data, type, and function declarations, is placed in a separate file called a **header file**. Type representations can be hidden by declaring them in the header file as pointers to struct types. The complete definitions of such struct types need only appear in the implementation file.

The header file, in source form, and the compiled version of the implementation file are furnished to clients. When such a library is used, the header file is included in the client code, using an `#include` preprocessor specification, so that references to functions and data in the client code can be type checked. The `#include` specification also documents the fact that the client program depends on the library implementation file. This approach effectively separates the specification and implementation of an encapsulation.

Although these encapsulations work, they create some insecurities. For example, a user could simply cut and paste the definitions from the header file into the client program, rather than using `#include`. This would work, because `#include` simply copies the contents of its operand file into the file in which the `#include` appears. However, there are two problems with this approach. First, the documentation of the dependence of the client program on the library (and its header file) is lost. Second, suppose a user copies the header file into his or her program. Then the author of the library changes both the header and the implementation files. Following this, the user uses the new implementation file with the old header. For example, a variable `x` could have been defined to be **`int`** type in the old header file, which the client code still uses, although the implementation code has been recompiled with

the new header file, which defines `x` to be **`float`**. So, the implementation code was compiled with `x` as an **`int`** but the client code was compiled with `x` as a **`float`**. The linker does not detect this error.

Thus, it is the user's responsibility to ensure that both the header and implementation files are up-to-date. This is often done with a `make` utility.

One other drawback of this approach is the inherent problems of pointers and the potential confusion with assignment and comparisons of pointers.

11.6.3 Encapsulation in C++

C++ provides two different kinds of encapsulation: header and implementation files can be defined as in C, or class headers and definitions can be defined. Because of the complex interplay of C++ templates and separate compilation, the header files of C++ template libraries often include complete definitions of resources, rather than just data declarations and subprogram protocols; this is due in part to the use of the C linker for C++ programs.

When nontemplated classes are used for encapsulations, the class header file has only the prototypes of the member functions, with the function - definitions provided outside the class in a code file, as in the last example in Section 11.4.1.4. This clearly separates interface from implementation.

One language design problem that results from having classes but no generalized encapsulation construct is that sometimes when operations are defined that use two different classes of objects, the operation does not naturally belong in either class. For example, suppose we have an abstract data type for matrices and one for vectors and need a multiplication operation between a vector and a matrix. The multiplication code must have access to the data members of both the vector and the matrix classes, but neither of those classes is the natural home for the code. Furthermore, regardless of which is chosen, access to the members of the other is a problem. In C++, these kinds of situations can be handled by allowing nonmember functions to be "friends" of a class. Friend functions have access to the private entities of

the class where they are declared to be friends. For the matrix/vector multiplication operation, one C++ solution is to define the operation outside both the matrix and the vector classes but define it to be a friend of both. The following skeletal code illustrates this scenario:

```
class Matrix;  //** A class declaration
class Vector {
  friend Vector multiply(const Matrix&, const Vector&);
  . . .
};
class  Matrix {  //** The class definition
  friend Vector multiply(const Matrix&, const Vector&);
  . . .
};
//** The function that uses both Matrix and Vector objects
Vector multiply(const Matrix& m1, const Vector& v1) {
  . . .
}
```

In addition to functions, whole classes can be defined to be friends of a class; then all the private members of the class are visible to all of the members of the friend class.

11.6.4 C# Assemblies

C# includes a larger encapsulation construct than a class. The construct is the one used by all of the .NET programming languages: the assembly. Assemblies are built by .NET compilers. A .NET application consists of one or more assemblies. An **assembly** is a file[4] that appears to application programs to be a single dynamic link library (`.dll`)[5] or an executable (`.exe`). An assembly defines a module, which can be separately developed. An assembly includes several different components. One of the primary components of an assembly is its programming code, which is in an intermediate language, having been compiled from its source language. In .NET, the intermediate language is named Common Intermediate Language (CIL). It is used by all .NET languages. Because its code is in CIL, an assembly can be used on any architecture, device, or operating system. When executed, the CIL is just-in-time compiled to native code for the architecture on which it is resident.

4. An assembly can consist of any number of files.

5. A **dynamic link library (DLL)** is a collection of classes and methods that are individually linked to an executing program when needed during execution. Therefore, although a program has access to all of the resources in a particular DLL, only the parts that are actually used are ever loaded and linked to the program. DLLs have been part of the Windows programming environment since Windows first appeared. However, the DLLs of .NET are quite different from those of previous Windows systems.

In addition to the CIL code, a .NET assembly includes metadata that describes every class it defines, as well as all external classes it uses. An assembly also includes a list of all assemblies referenced in the assembly and an assembly version number.

In the .NET world, the assembly is the basic unit of deployment of software. Assemblies can be private, in which case they are available to just one application, or public, which means any application can use them.

As mentioned previously, C# has an access modifier, **`internal`**. An **`internal`** member of a class is visible to all classes in the assembly in which it appears.

Java has a file structure that is similar to an assembly called a Java Archive (JAR). It is also used for deployment of Java software systems. JARs are built with the Java utility `jar`, rather than a compiler.

11.7 Naming Encapsulations

We have considered encapsulations to be syntactic containers for logically related software resources—in particular, abstract data types. The purpose of these encapsulations is to provide a way to organize programs into logical units for compilation. This allows parts of programs to be recompiled after isolated changes. There is another kind of encapsulation that is necessary for constructing large programs: a naming encapsulation.

A large program is usually written by many developers, working somewhat independently, perhaps even in different geographic locations. This requires the logical units of the program to be independent, while still able to work together. It also creates a naming problem: How can independently working developers create names for their variables, methods, and classes without accidentally using names already in use by some other programmer developing a different part of the same software system?

Libraries are the origin of the same kind of naming problems. Over the past two decades, large software systems have become progressively more dependent on libraries of supporting software. Nearly all software written in contemporary programming languages requires the use of large and complex standard libraries, in addition to application-specific libraries. This widespread use of multiple libraries has necessitated new mechanisms for managing names. For example, when a developer adds new names to an existing library or creates a new library, he or she must not use a new name that conflicts with a name already defined in a client's application program or in some other library the program uses. Without some language processor assistance, this is virtually impossible, because there is no convenient way for the library author to know what names a client's program uses or what names are defined by the other libraries the client program might use.

Naming encapsulations define name scopes that assist in avoiding these name conflicts. Each library can create its own naming encapsulation to prevent its names from conflicting with the names defined in other libraries or in client code. Each logical part of a software system can create a naming

encapsulation with the same purpose.

Naming encapsulations are logical encapsulations, in the sense that they need not be physically contiguous. Several different collections of code can be placed in the same namespace, even though they are stored in different places. In the following sections, we briefly describe the uses of naming encapsulations in C++, Java, and Ruby.

11.7.1 C++ Namespaces

C++ includes a specification, **`namespace`**, that helps programs manage the problem of global namespaces. One can place each library in its own namespace and qualify the names in the program with the name of the namespace when the names are used outside that namespace. For example, suppose there is an abstract data type header file that implements stacks. If there is concern that some other library file may define a name that is used in the stack abstract data type, the file that defines the stack could be placed in its own namespace. This is done by placing all of the declarations for the stack in a namespace block, as in the following:

```
namespace myStackSpace {
  // Stack declarations
}
```

The implementation file for the stack abstract data type could reference the names declared in the header file with the scope resolution operator, `::`, as in

```
myStackSpace::topSub
```

The implementation file could also appear in a namespace block specification identical to the one used on the header file, which would make all of the names declared in the header file directly visible. This is definitely simpler, but slightly less readable, because it is less obvious where a specific name in the implementation file is declared.

Client code can gain access to the names in the namespace of the header file of a library in three different ways. One way is to qualify the names from the

library with the name of the namespace. For example, a reference to the variable `topSub` could appear as follows:

```
myStackSpace::topSub
```

This is exactly the way the implementation code could reference it if the implementation file was not in the same namespace.

The other two approaches use the **`using`** directive. This directive can be used to qualify individual names from a namespace, as with

```
using myStackSpace::topSub;
```

which makes `topSub` visible, but not any other names from the `myStackSpace` namespace.

The **`using`** directive also can be used to qualify all of the names from a namespace, as in the following:

```
using namespace myStackSpace;
```

Code that includes this directive can directly access the names defined in the namespace, as in

```
p = topSub;
```

Be aware that namespaces are a complicated feature of C++, and we have introduced only the simplest part of the story here.

C# includes namespaces that are much like those of C++.

11.7.2 Java Packages

Java includes a naming encapsulation construct: the package. Packages can contain more than one type[6] definition, and the types in a package are partial friends of one another. *Partial* here means that the entities defined in a type in a package that either are public or protected (see Chapter 12) or have no access specifier are visible to all other types in the package.

6. By type here we mean either a class or an interface.

Entities without access modifiers are said to have **package scope**, because they are visible throughout the package. Java therefore has less need for explicit friend declarations and does not include the friend functions or friend classes of C++.

The resources defined in a file are specified to be in a particular package with a package declaration, as in

```
package stkpkg;
```

The package declaration must appear as the first line of the file. The resources of every file that does not include a package declaration are implicitly placed in the same unnamed package.

The clients of a package can reference the types defined in the package using fully qualified names. For example, if the package `stkpkg` has a class named `myStack`, that class can be referenced in a client of `stkpkg` as `stkpkg.myStack`. Likewise, a variable in the `myStack` object named `topSub` could be referenced as `stkpkg.myStack.topSub`. Because this approach can quickly become cumbersome when packages are nested, Java provides the **`import`** declaration, which allows shorter references to type names defined in a package. For example, suppose the client includes the following:

```
import stkpkg.myStack;
```

Now, the class `myStack` can be referenced by just its name. To be able to access all of the type names in the package, an asterisk can be used on the import statement in place of the type name. For example, if we wanted to import all of the types in `stkpkg`, we could use the following:

```
import stkpkg.*;
```

Note that Java's **`import`** is only an abbreviation mechanism. No otherwise hidden external resources are made available with **`import`**. In fact, in Java nothing is implicitly hidden if it can be found by the compiler or class loader (using the package name and the `CLASSPATH` environment variable).

Java's **import** documents the dependencies of the package in which it appears on the packages named in the **import**. These dependencies are less obvious when **import** is not used.

11.7.3 Ruby Modules

Ruby classes serve as namespace encapsulations, as do the classes of other languages that support object-oriented programming. Ruby has an additional naming encapsulation, called a **module**. Modules typically define collections of methods and constants. So, modules are convenient for encapsulating libraries of related methods and constants, whose names are in a separate namespace so there are no name conflicts with other names in a program that uses the module. Modules are unlike classes in that they cannot be instantiated or subclassed and do not define variables. Methods that are defined in a module include the module's name in their names. For example, consider the following skeletal module definition:

```
module MyStuff
  PI = 3.14159265
  def MyStuff.mymethod1(p1)
  . . .
  end
  def MyStuff.mymethod2(p2)
  . . .
  end
end
```

Assuming the `MyStuff` module is stored in its own file, a program that wants to use the constant and methods of `MyStuff` must first gain access to the module. This is done with the `require` method, which takes the file name in the form of a string literal as a parameter. Then, the constants and methods of the module can be accessed through the module's name. Consider the following code that uses our example module, `MyStuff`, which is stored in the file named `myStuffMod`:

```
  require 'myStuffMod'
  . . .
  MyStuff.mymethod1(x)
  . . .
```

Modules are further discussed in Chapter 12.

SUMMARY

The concept of abstract data types, and their use in program design, was a milestone in the development of programming as an engineering discipline. Although the concept is relatively simple, its use did not become convenient and safe until languages were designed to support it.

The two primary features of abstract data types are the packaging of data objects with their associated operations and information hiding. A language may support abstract data types directly or simulate them with more general encapsulations.

C++ data abstraction is provided by classes. Classes are types, and instances can be either stack or heap dynamic. A member function (method) can have its complete definition appear in the class or have only the protocol given in the class and the definition placed in another file, which can be separately compiled. C++ classes can have two clauses, each prefixed with an access modifier: private or public. Both constructors and destructors can be given in class definitions. Heap-allocated objects must be explicitly deallocated with **`delete`**.

Java data abstractions are similar to those of C++, except all Java objects are allocated from the heap and are accessed through reference variables. Also, all objects are garbage collected. Rather than having access modifiers attached to clauses, in Java the modifiers appear on individual declarations (or definitions).

C# supports abstract data types with both classes and structs. Its structs are value types and do not support inheritance. C# classes are similar to those of Java.

Ruby supports abstract data types with its classes. Ruby's classes differ from those of most other languages in that they are dynamic—members can be added, deleted, or changed during execution.

C++, Java 5.0, and C# 2005 allow their abstract data types to be -parameterized—Ada through its generic packages, C++ through its templated classes, and Java 5.0 and C# through their collection classes and interfaces and user-defined generic classes.

To support the construction of large programs, some contemporary languages include multiple-type encapsulation constructs, which can contain a collection of logically related types. An encapsulation may also provide access control to its entities. Encapsulations provide the programmer with a method of organizing programs that also facilitates recompilation.

C++, C#, Java, and Ruby provide naming encapsulations. For Ada and Java, they are named packages; for C++ and C#, they are namespaces; for Ruby, they are modules. Partially because of the availability of packages, Java does not have friend functions or friend classes.

REVIEW QUESTIONS

1. What are the two kinds of abstractions in programming languages?
2. Define *abstract data type*.
3. What are the advantages of the two parts of the definition of *abstract data type*?
4. What are the language design requirements for a language that supports abstract data types?
5. What are the language design issues for abstract data types?
6. From where are C++ objects allocated?
7. In what different places can the definition of a C++ member function appear?
8. What is the purpose of a C++ constructor?
9. What are the legal return types of a constructor?
10. Where are all Java methods defined?
11. How are C++ class instances created?
12. From where are Java class instances allocated?
13. Why does Java not have destructors?
14. Where are all Java methods defined?
15. Where are Java classes allocated?
16. Why are destructors not as frequently needed in Java as they are in C++?

17. What is a friend function? What is a friend class?

18. What is one reason Java does not have friend functions or friend classes?

19. Describe the fundamental differences between C# structs and its classes.

20. How is a struct object in C# created?

21. Explain the three reasons accessors to private types are better than making the types public.

22. What are the differences between a C++ struct and a C# struct?

23. What is the name of all Ruby constructors?

24. What is the fundamental difference between the classes of Ruby and those of C++ and Java?

25. How are instances of C++ template classes created?

26. Describe the two problems that appear in the construction of large programs that led to the development of encapsulation constructs.

27. What problems can occur using C to define abstract data types?

28. What is a C++ namespace, and what is its purpose?

29. What is a Java package, and what is its purpose?

30. Describe a .NET assembly.

31. What elements can appear in a Ruby module?

PROBLEM SET

1. Some software engineers believe that all imported entities should be qualified by the name of the exporting program unit. Do you agree? Support your answer.

2. Suppose someone designed a stack abstract data type in which the function `top` returned an access path (or pointer) rather than returning a copy of the top element. This is not a true data abstraction. Why? Give an example that illustrates the problem.

3. Write an analysis of the similarities of and differences between Java packages and C++ namespaces.

4. Discuss the advantages of C# properties, relative to writing accessor methods in C++ or Java.

5. Explain the dangers of C's approach to encapsulation.

6. Why didn't C++ eliminate the problems discussed in Problem 5?

7. Why are destructors rarely used in Java but essential in C++?

8. What are the arguments for and against the C++ policy on inlining of methods?

9. Describe a situation where a C# struct is preferable to a C# class.

10. Explain why naming encapsulations are important for developing large programs.

11. Describe the three ways a client can reference a name from a namespace in C++.

12. The namespace of the C# standard library, `System`, is not implicitly available to C# programs. Do you think this is a good idea? Defend your

answer.

13. What are the advantages and disadvantages of the ability to change objects in Ruby?

14. Compare Java’s packages with Ruby’s modules.

PROGRAMMING EXERCISES

1. Design an abstract data type for a matrix with integer elements in a language that you know, including operations for addition, subtraction, and matrix multiplication.

2. Design a queue abstract data type for float elements in a language that you know, including operations for enqueue, dequeue, and empty. The dequeue operation removes the element and returns its value.

3. Modify the C++ class for the abstract stack type shown in Section 11.4.1 to use a linked list representation and test it with the same code that appears in this chapter.

4. Modify the Java class for the abstract stack type shown in Section 11.4.2 to use a linked list representation and test it with the same code that appears in this chapter.

5. Write an abstract data type for complex numbers, including operations for addition, subtraction, multiplication, division, extraction of each of the parts of a complex number, and construction of a complex number from two floating-point constants, variables, or expressions. Use C++, Java, C#, or Ruby.

6. Write an abstract data type for queues whose elements store 10-character names. The queue elements must be dynamically allocated from the heap. Queue operations are enqueue, dequeue, and empty. Use either C++, Java, C#, or Ruby.

7. Write an abstract data type for a queue whose elements can be any primitive type. Use Java 5.0, C# 2005, or C++.

8. Write an abstract data type for a queue whose elements include both a 20-character string and an integer priority. This queue must have the following methods: enqueue, which takes a string and an integer as parameters; dequeue, which returns the string from the queue that has

the highest priority; and empty. The queue is not to be maintained in priority order of its elements, so the dequeue operation must always search the whole queue.

9. A deque is a double-ended queue, with operations adding and removing elements from either end. Modify the solution to Programming Exercise 7 to implement a deque.

10. Write an abstract data type for rational numbers (a numerator and a denominator). Include a constructor and methods for getting the numerator, getting the denominator, addition, subtraction, multiplication, division, equality testing, and display. Use Java, C#, C++, or Ruby.

12 Support for Object-Oriented Programming

This chapter begins with a brief introduction to object-oriented programming, followed by an extended discussion of the primary design issues for inheritance and dynamic binding. Next, the support for object-oriented programming in Smalltalk, C++, Java, C#, and Ruby is discussed. Following this is a short overview of the implementation of dynamic bindings of method calls to methods in object-oriented languages. The last section discusses reflection.

12.1 Introduction

Languages that support object-oriented programming now are firmly entrenched in the mainstream. From COBOL to LISP, including virtually every language in between, dialects that support object-oriented programming have appeared. C++ supports procedural and data-oriented programming, in addition to object-oriented programming. CLOS, an object-oriented version of LISP (Paepeke, 1993), also supports functional programming. Some of the newer languages that were designed to support object-oriented programming do not support other programming paradigms but still employ some of the basic imperative structures and have the appearance of the older imperative languages. Among these are Java and C#. Ruby is challenging to categorize: It is a pure object-oriented language in the sense that all data are objects, but it is a hybrid language in that one can use it for procedural programming. Finally, there is the pure object-oriented but somewhat unconventional language: Smalltalk. Smalltalk was the first language to offer complete support for object-oriented programming. The details of support for object-oriented programming vary widely among languages, and that is the primary topic of this chapter.

This chapter relies heavily on Chapter 11. It is in fact a continuation of that chapter. This relationship reflects the reality that object-oriented programming is, in essence, an application of the principle of abstraction to abstract data types. Specifically, in object-oriented programming, the commonality of a collection of similar abstract data types is factored out and put in a new type. The members of the collection inherit these common parts from that new type. This feature is inheritance, which is at the center of object-oriented programming and the languages that support it.

The other characterizing feature of object-oriented programming, dynamic binding of method calls to methods, is also extensively discussed in this chapter.

Although object-oriented programming is supported by some of the functional languages, for example, CLOS, OCaml, and F#, those languages

are not discussed in this chapter.

12.2 Object-Oriented Programming

12.2.1 Introduction

The concept of **object-oriented programming** had its roots in SIMULA 67 but was not fully developed1 until the evolution of Smalltalk resulted in Smalltalk 80 (in 1980, of course). Indeed, some consider Smalltalk to be the base model for a purely object-oriented programming language. A language that is object oriented must provide support for three key language features: abstract data types, inheritance, and dynamic binding of method calls to methods. Abstract data types were discussed in detail in Chapter 11, so this chapter focuses on inheritance and dynamic binding.

1. Although SIMULA 67 had classes, the members defined inside them were not hidden from outside code.

12.2.2 Inheritance

There has long been pressure on software developers to increase their productivity. This pressure has been intensified by the continuing reduction in the cost of computer hardware. By the middle to late 1980s, it became apparent to many software developers that one of the most promising opportunities for increased productivity in their profession was in software reuse. Abstract data types, with their encapsulation and access controls, are obvious candidates for reuse. The problem with the reuse of abstract data types is that, in nearly all cases, the features and capabilities of the existing type are not quite right for the new use. The old type requires at least some minor modifications. Such modifications can be difficult, because they require the person doing the modification to understand part, if not all, of the existing code. In many cases, the person doing the modification is not the program's original author. Furthermore, the modifications often require changes to all client programs.

A second problem with programming with abstract data types is that the type definitions are all independent and are at the same level.2 This design often makes it impossible to organize a program to match the problem space being addressed by the program. In many cases, the underlying problem has categories of objects that are related, both as siblings (being similar to each other) and as parents and children (having a descendant relationship).

2. This is similar to the functions in a C program, which are also independent and at a single level.

Inheritance offers a solution to both the modification problem posed by abstract data type reuse and the program organization problem. If a new abstract data type can inherit the data and functionality of some existing type, and is also allowed to modify some of those entities and add new entities, reuse is greatly facilitated without requiring changes to the reused abstract data type. Programmers can begin with an existing abstract data type and design a modified descendant of it to fit a new problem requirement. Furthermore, inheritance provides a framework for the definition of hierarchies of related classes that can reflect the descendant relationships in the problem space.

The abstract data types in object-oriented languages, following the lead of SIMULA 67, are usually called **classes**. As with instances of abstract data types, class instances are called **objects**. A class that is defined through inheritance from another class is a **derived class**, a **subclass**, or a **child class**. A class from which the new class is derived is its **base class**, **superclass**, or **parent class**. The subprograms that define the operations on objects of a class are called **methods**. The calls to methods are sometimes called **messages**. The entire collection of methods of a class is called the **message protocol**, or **message interface**, of the class. Computations in an object-oriented program are specified by messages sent from objects to other objects, or in some cases, to classes.

Methods are similar to subprograms. Both are collections of code that perform some computation. Both can take parameters and return results.

Passing a message is different from calling a subprogram. A subprogram typically processes data that is either passed to it by its caller as a parameter

or is accessed nonlocally or globally. A message that is sent to an object is a request to execute one of its methods. At least some of the data on which the method is to operate is part of the object itself. Objects have methods that define processes the object can perform on itself. Because the objects are of abstract data types, these should be the only ways to manipulate data of the object. A subprogram defines a process that it can perform on any data sent to it (or made available nonlocally or globally).

As a simple example of inheritance, consider the following: Suppose we have a class named `Vehicles`, which has variables for year, color, and make. A natural specialization, or subclass, of this would be `Truck`, which could inherit the variables from `Vehicle`, but would add variables for hauling capacity and number of wheels. Figure 12.1 shows a simple diagram to indicate the relationship between the `Vehicle` class and the `Truck` class, in which the arrow points to the parent class.

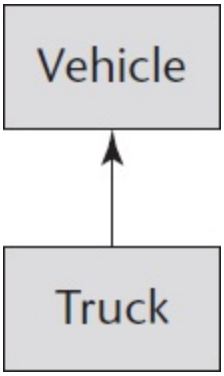

Figure 12.1 A simple example of inheritance

There are several ways a derived class can differ from its parent.3 Following are the most common differences between a parent class and its subclasses:

3. If a subclass does not differ from its parent, it obviously serves no purpose.

1. The subclass can add variables and/or methods to those inherited from the parent class.

2. The subclass can modify the behavior of one or more of its inherited methods. A modified method has the same name, and often the same protocol, as the one of which it is a modification.

3. The parent class can define some of its variables or methods to have private access, which means they will not be visible in the subclass.

The new method is said to **override** the inherited method, which is then called an **overridden method**. The purpose of an overriding method is to provide an operation in the subclass that is similar to one in the parent class, but is customized for objects of the subclass. For example, a parent class, `Bird`, might have a `draw` method that draws a generic bird. A subclass of `Bird` named `Waterfowl` could override the `draw` method inherited from `Bird` to draw a generic waterfowl, perhaps a duck.

Classes can have two kinds of methods and two kinds of variables. The most commonly used methods and variables are called **instance methods** and **instance variables**. Every object of a class has its own set of instance variables, which store the object's state. The only difference between two objects of the same class is the state of their instance variables.4 For example, a class for cars might have instance variables for color, make, model, and year. Instance methods operate only on the objects of the class. **Class variables** belong to the class, rather than their objects, so there is only one copy for the class. For example, if we wanted to count the number of instances of a class, the counter could not be an instance variable—it would need to be a class variable. **Class methods** can perform operations on the class, and possibly also on the objects of the class. They can be called by prefixing their names with either the class name or a variable that references one of their instances. If a class defines a class method, that method can be called even if there are no instances of the class. A class method could be used to create an instance of the class.

4. This is not true in Ruby, which allows different objects of the same class to differ in other ways.

If a new class is a subclass of a single parent class, then the derivation process is called **single inheritance**. If a class has more than one parent class, the process is called **multiple inheritance**. When a number of classes are

related through single inheritance, their relationships to each other can be shown in a derivation tree. The class relationships in a multiple inheritance can be shown in a derivation graph. This is shown in Figure 12.5 in Section 12.4.2.2.

One disadvantage of inheritance as a means of increasing the possibility of reuse is that it creates dependencies among the classes in an inheritance hierarchy. This result works against one of the advantages of abstract data types, which is that they are independent of each other. Of course, not all abstract data types must be completely independent. But in general, the independence of abstract data types is one of their strongest positive characteristics. However, it may be difficult, if not impossible, to increase the reusability of abstract data types without creating dependencies among some of them. Furthermore, in many cases, the dependencies naturally mirror dependencies in the underlying problem space.

In Chapter 11 the access controls for variables and methods, together often called members, in a class are discussed. Private members are visible inside the class, while public members also are visible to clients of the class. Inheritance brings a new category of possible visibility, subclasses. Private members of a base class are not visible to subclasses, but public members are. The third level of accessibility, protected, allows members of a base class to be visible to subclasses, but not clients.

12.2.3 Dynamic Binding

The third essential characteristic (after abstract data types and inheritance) of object-oriented programming languages is a kind of polymorphism[5] provided by the dynamic binding of messages to method definitions. This is sometimes called **dynamic dispatch**. Consider the following situation: There is a base class, `A`, that defines a method `draw` that draws some figure associated with the base class. A second class, `B`, is defined as a subclass of `A`. Objects of this new class also need a `draw` method that is like that provided by `A` but a bit different because the subclass objects are slightly different. So, the subclass overrides the inherited `draw` method. If a client of `A` and `B` has a variable that is a reference to class `A`'s objects, that reference also could point at class `B`'s

objects, making it a **polymorphic** reference. If the method `draw`, which is defined in both classes, is called through the polymorphic reference, the run-time system must determine, during execution, which method should be called, `A`'s or `B`'s (by determining which type object is currently referenced by the reference).6 Figure 12.2 shows this situation.

6. Dynamic binding of method calls to methods is sometimes called *dynamic polymorphism*.

5. Polymorphism is defined in Chapter 9.

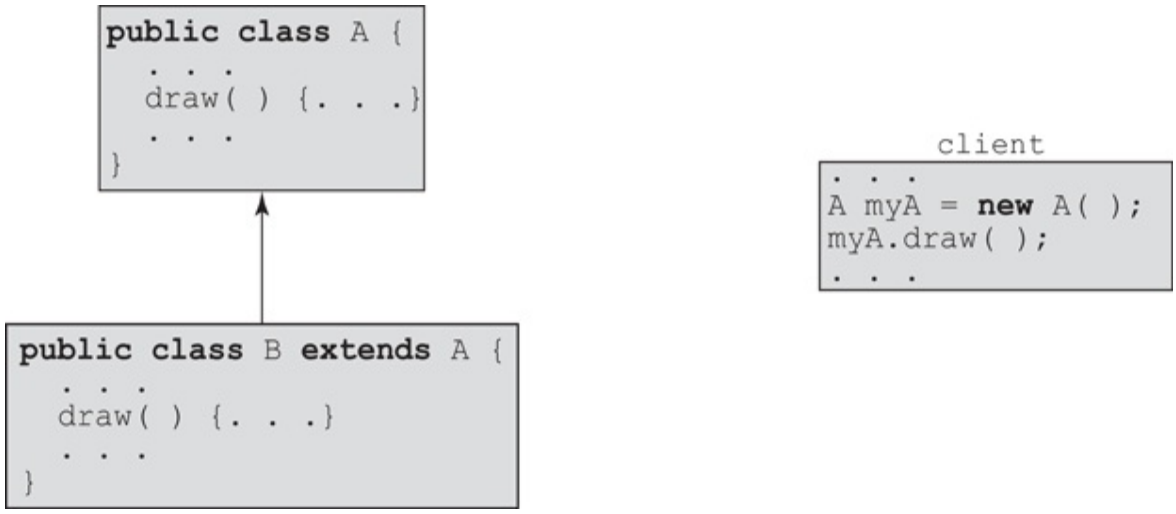

Figure 12.2 Dynamic binding

Figure 12.2 Full Alternative Text

Polymorphism is a natural part of any object-oriented language that is statically typed. In a sense, polymorphism makes a statically typed language a little bit dynamically typed, where the little bit is in some bindings of method calls to methods. The type of a polymorphic variable is indeed dynamic.

One purpose of dynamic binding is to allow software systems to be more easily extended during both development and maintenance. Suppose we have a catalog of used cars that is implemented as a `Car` class and a subclass for

each car in the catalog. The subclasses contain an image of the car and specific information about the car. Users can browse the cars with a program that displays the images and information about each car as the user browses to it. The display of each car (and its information) includes a button that the user can click if he or she is interested in that particular car. After the user gets through the catalog, the system will print the images and information about the cars of interest to the user. One way to implement this system is to place a reference to each car (subclass of `Car`) of interest in a list that can store references to the base class, `Car`. When the user is ready, information about all of the cars of interest could be printed for the user to study and compare the cars in the list. The catalog of cars will of course change frequently. This will necessitate corresponding changes in the subclasses of `Car`. However, changes to the collection of subclasses will not require any other changes to the system.

In some cases, the design of an inheritance hierarchy results in one or more classes that are so high in the hierarchy that an instantiation of them would not make sense. For example, suppose a program defined a `Building` class and a collection of subclasses for specific types of buildings, for instance, `French_Gothic_Cathedrals`. It probably would not make sense to have an implemented `draw` method in `Building`. But because all of its descendant classes should have such methods, the protocol (but not the body) of that method is included in `Building`. Such a method is often called an **abstract method** (*pure virtual method* in C++). A class that includes at least one abstract method is called an **abstract class** (*abstract base class* in C++). Such a class usually cannot be instantiated, because some of its methods are declared but are not defined (they do not have bodies). Any subclass of an abstract class that is to be instantiated must provide implementations (definitions) of all of the inherited abstract methods.

12.3 Design Issues for Object-Oriented Languages

A number of issues must be considered when designing the programming language features to support inheritance and dynamic binding. Those that we consider most important are discussed in this section.

12.3.1 The Exclusivity of Objects

A language designer who is totally committed to the object model of computation designs an object system that subsumes all other concepts of type. Everything, from a simple scalar integer to a complete software system, is an object in this mind-set. The advantage of this choice is the elegance and pure uniformity of the language and its use. The primary disadvantage is that simple operations must be done through the message-passing process, which often makes them slower than similar operations in an imperative model, where single machine instructions may implement such simple operations. In this purest model of object-oriented computation, all types are classes. There is no distinction between predefined and user-defined classes. In fact, all classes are treated the same way and all computation is accomplished through message passing.

One alternative to the exclusive use of objects that is common in imperative languages to which support for object-oriented programming has been added is the following: Retain the complete collection of types from the base imperative language and add the object typing model. This approach results in a larger language whose type structure can be confusing to new users of the language.

Another alternative to the exclusive use of objects is to have an imperative-style type structure for the primitive scalar types, but implement all structured types as objects. This choice provides the speed of operations on primitive

values that is comparable to those expected in the imperative model.

12.3.2 Are Subclasses Subtypes?

If a language allows programs in which a variable of a class can be substituted for a variable of one of its ancestor classes in any situation, without causing type errors and without changing the behavior of the program, that language supports the **principle of substitution**. In such a language, if class `B` is derived from class `A`, then `B` has everything `A` has and the behavior of an object of class `B`, when used in place of an object of class `A`, is identical to that of an object of class `A`.[7] When this is true, `B` is a **subtype** of `A`. Although a subclass that is a subtype of its parent class must expose all of the members that are exposed by its parent class, the subclass can have members that are not in the parent class and still be a subtype.

7. There is a fundamental theoretical problem with this last requirement: In general, it is not possible to determine if the behaviors of two programs are identical.

The subtypes of Ada are examples of predefined subtypes. For example,

```
subtype Small_Int is Integer range -100..100;
```

Variables of `Small_Int` type have all of the operations of `Integer` variables but can store only a subset of the values possible in `Integer`. Furthermore, every `Small_Int` variable can be used anywhere an `Integer` variable can be used. That is, every `Small_Int` variable is, in a sense, an `Integer` variable.

The definition of subtype clearly disallows having public entities in the parent class that are not public in the subclass. So, the derivation process for subtypes must require that public entities of the parent class are inherited as public entities in the subclass.

Not all subclasses are subtypes and not all subtypes are subclasses. For example, a subclass cannot be a subtype if it changes the behavior of one of its overriding methods. Also, a class that is not a subclass of another class can be a subtype of that class by defining the same members, in terms of both

types and behavior. A subtype inherits interfaces and behavior, while a subclass inherits implementation, primarily to promote code reuse.

Most static-typed languages that support object-oriented programming are designed so that subclasses are subtypes, unless the programmer specifically designs a subclass that has behavior that differs from that of its parent class.

One obvious question is: Is the issue of whether subclasses are subtypes a theoretical or practical one? It is probably unusual to define a subclass whose overriding methods preserve the type protocols of their corresponding overridden methods but not their effects. So it is not a frequent practical issue. However, requiring all subclasses to be subtypes, if there were a reasonably simple way to enforce that, would place inheritance on a sounder theoretical base.

12.3.3 Single and Multiple Inheritance

Another simple design issue for object-oriented languages is: Does the language allow multiple inheritance (in addition to single inheritance)? Maybe it’s not so simple. The purpose of multiple inheritance is to allow a new class to inherit from two or more classes.

Because multiple inheritance is sometimes highly useful, why would a language designer not include it? The reasons lie in two categories: complexity and efficiency. The additional complexity is illustrated by several problems. First, note that if a class has two unrelated parent classes and neither defines a name that is defined in the other, there is no problem. However, suppose a subclass named `C` inherits from both class `A` and class `B` and both `A` and `B` define an inheritable method named `display`. If `C` needs to reference both versions of `display`, how can that be done? This ambiguity problem is further complicated when the two parent classes both define identically named methods and one or both of them must be overridden in the subclass.

Another issue arises if both `A` and `B` are derived from a common parent, `Z`, and `C` has both `A` and `B` as parent classes. This situation is called **diamond** or **shared** inheritance. In this case, both `A` and `B` should include `Z`'s inheritable variables. Suppose `Z` includes an inheritable variable named `sum`. The question is whether `C` should inherit both versions of `sum` or just one, and if just one, which one? There may be programming situations in which just one of the two should be inherited, and others in which both should be inherited. A similar problem occurs when both `A` and `B` inherit a method from `Z` and both override that method. If a client of `C`, which inherits both overriding methods, calls the method, which method is called, or are both supposed to be called. Diamond inheritance is shown in Figure 12.3.

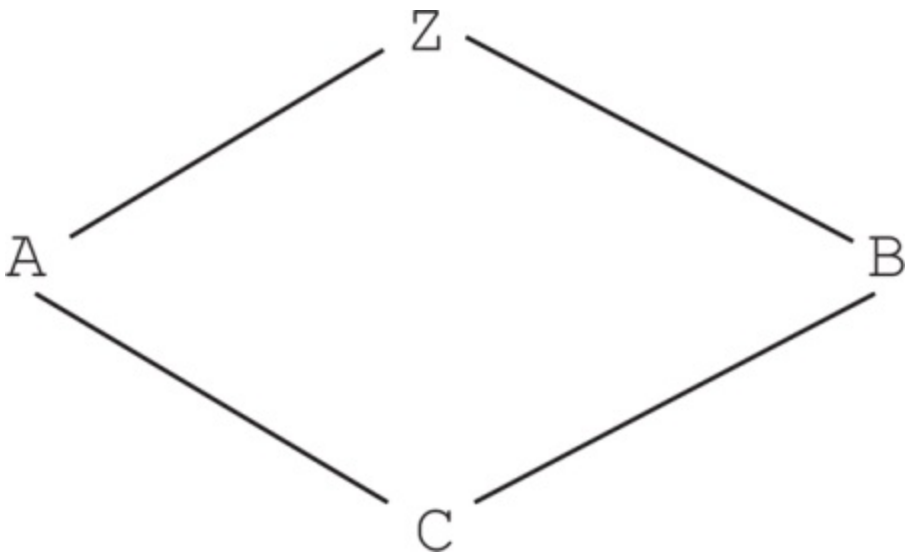

Figure 12.3 An example of diamond inheritance

The question of efficiency may be more perceived than real. In C++, for example, supporting multiple inheritance requires just one additional array access and one extra addition operation for each dynamically bound method call, at least with some machine architectures (Stroustrup, 1994, p. 270). Although this operation is required even if the program does not use multiple inheritance, it is a small additional cost.

The use of multiple inheritance can easily lead to complex program organizations. Many who have attempted to use multiple inheritance have found that designing the classes to be used as multiple parents is difficult. And the difficulties are not restricted to those created by the initial developer. A class might be used by another developer at some later date as one of the parents of a new class. Maintenance of systems that use multiple inheritance can be a more serious problem, for multiple inheritance leads to more complex dependencies among classes. It is not clear to some that the benefits of multiple inheritance are worth the added effort to design and maintain a system that uses it.

An interface is somewhat similar to an abstract class; its methods are declared but not defined. Interfaces cannot be instantiated. They are used as an alternative to multiple inheritance.8 Interfaces provide some of the benefits of multiple inheritance but have fewer disadvantages. For example, the problems of diamond inheritance are avoided when interfaces, rather than multiple inheritance, are used.

8. Interfaces initially appeared in Java, whose designers recognized the difficulties that are raised by the use of multiple inheritance.

12.3.4 Allocation and Deallocation of Objects

There are two design questions concerning the allocation and deallocation of objects. The first of these is the place from which objects are allocated. If they behave like the abstract data types, then they can be allocated from anywhere. This means they could be allocated from the run-time stack or explicitly created on the heap with an operator or function, such as **new**. If they are all heap dynamic, there is the advantage of having a uniform method of creation and access through pointer or reference variables. This design simplifies the assignment operation for objects, making it in all cases only a pointer or reference value change. It also allows references to objects to be implicitly dereferenced, simplifying the access syntax.

If objects are stack dynamic, there is a potential problem with regard to subtypes. If class `B` is a child of class `A` and `B` is a subtype of `A`, then an object of `B` type can be assigned to a variable of `A` type. For example, if `b1` is a variable of `B` type and `a1` is a variable of `A` type, then

```
a1 = b1;
```

is a legal statement. If `a1` and `b1` are references to heap-dynamic objects, there is no problem—the assignment is a simple pointer assignment. However, if `a1` and `b1` are stack dynamic, then they are value variables and, if assigned the value of the object, must be copied to the space of the target object. If `B` adds a data field to what it inherited from `A`, then `a1` will not have sufficient space on the stack for all of `b1`. The excess will simply be truncated, which could be confusing to programmers who write or use the code. This truncation is called **object slicing**. The following example and Figure 12.4 illustrate the problem.

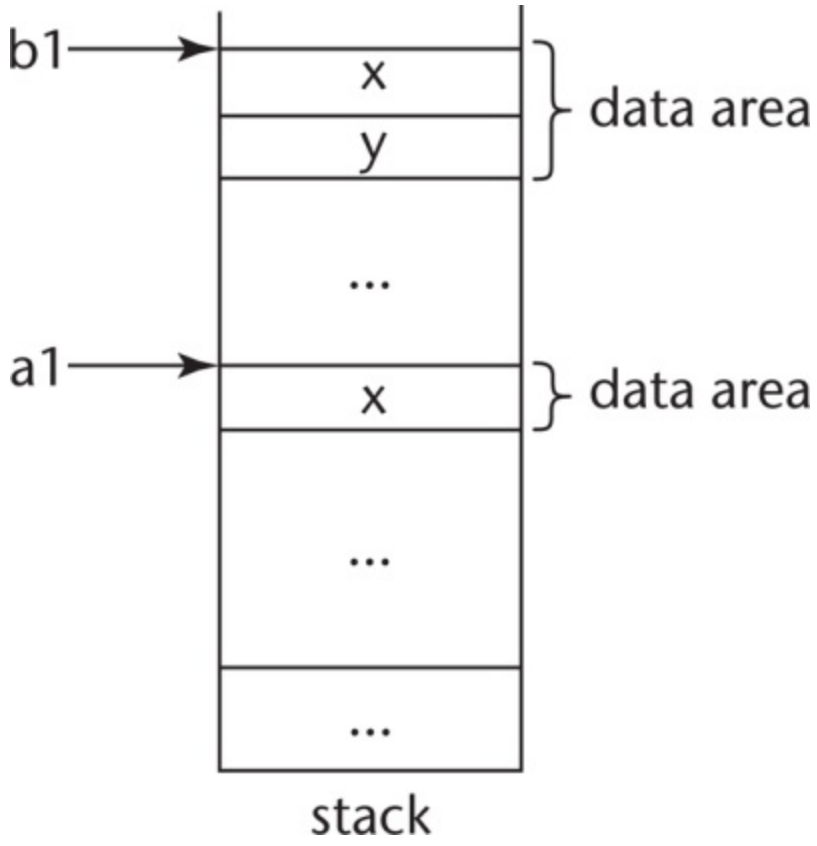

Figure 12.4 An example of object slicing

Figure 12.4 Full Alternative Text

```
class A {
  int x;
  . . .
};
class B : A {
  int y;
  . . .
}
```

The second question here is concerned with those cases where objects are allocated from the heap. The question is whether deallocation is implicit, explicit, or both. If deallocation is implicit, some implicit method of storage reclamation is required. If deallocation can be explicit, that raises the issue of whether dangling pointers or references can be created.

12.3.5 Dynamic and Static Binding

As discussed in Section 12.2.3, dynamic binding of messages to methods is an essential part of object-oriented programming. The question here is whether all bindings of messages to methods are dynamic. The alternative is to allow the user to specify whether a specific binding is to be dynamic or static. The advantage of this is that static bindings are faster. So, if a binding need not be dynamic, why pay the price?

12.3.6 Nested Classes

One of the primary motivations for nesting class definitions is information hiding. If a new class is needed by only one class, there is no reason to define it so it can be seen by other classes. In this situation, the new class can be

nested inside the class that uses it. In some cases, the new class is nested inside a subprogram, rather than directly in another class.

The class in which the new class is nested is called the **nesting class**. The most obvious design issues associated with class nesting are related to visibility. Specifically, one issue is: Which of the members of the nesting class are visible in the nested class? The other important issue is the opposite: Which of the members of the nested class are visible in the nesting class?

12.3.7 Initialization of Objects

The initialization issue is whether and how objects are initialized to values when they are created. This is more complicated than may be first thought. One question is whether objects must be initialized manually or through some implicit mechanism. When an object of a subclass is created, is the associated initialization of the inherited parent class member implicit or must the programmer explicitly deal with it?

12.4 Support for Object-Oriented Programming in Specific Languages

12.4.1 Smalltalk

Many think of Smalltalk as the definitive object-oriented programming language. It was the first language to include complete support for that paradigm. Therefore, it is natural to begin a survey of language support for object-oriented programming with Smalltalk.

12.4.1.1 General Characteristics

In Smalltalk, the concept of an object is truly universal. Virtually everything, from things as simple as the integer constant `2` to a complex file-handling system, is an object. As objects, they are treated uniformly. They all have local memory, inherent processing ability, the capability to communicate with other objects, and the possibility of inheriting methods and instance variables from ancestors. Classes cannot be nested in Smalltalk.

All computation is through messages, even a simple arithmetic operation. For example, the expression `x + 7` is implemented as sending the `+` message to `x` (to enact the `+` method), sending `7` as the parameter. This operation returns a new numeric object with the result of the addition.

Replies to messages have the form of objects and are used to return requested or computed information or only to confirm that the requested service has been completed.

All Smalltalk objects are allocated from the heap and are referenced through reference variables, which are implicitly dereferenced. There is no explicit deallocation statement or operation. So, all deallocation is implicit, using a

garbage collection process for storage reclamation.

In Smalltalk, constructors must be explicitly called when an object is created. A class can have multiple constructors, but each must have a unique name.

Smalltalk classes cannot be nested in other classes.

Unlike a hybrid language such as C++, Smalltalk was designed for just one software development paradigm—object oriented. Furthermore, it adopts none of the appearance of the imperative languages. Its purity of purpose is reflected in its simple elegance and uniformity of design.

There is an example Smalltalk program in Chapter 2.

12.4.1.2 Inheritance

A Smalltalk subclass inherits all of the members of its superclass. The subclass can also have its own instance variables, which must have names that are distinct from the variable names in its ancestor classes. Finally, the subclass can define new methods and redefine methods that already exist in an ancestor class. When a subclass has a method whose name and protocol are the same as an ancestor class, the subclass method hides that of the ancestor class. Access to such a hidden method is provided by prefixing the message with the pseudovariable **`super`**. The prefix causes the method search to begin in the superclass rather than locally.

Because members in a parent class cannot be hidden from subclasses, subclasses can be and usually are subtypes.

Smalltalk does not support multiple inheritance.

12.4.1.3 Dynamic Binding

The dynamic binding of messages to methods in Smalltalk operates as follows: A message to an object causes a search of the class to which the

object belongs for a corresponding method. If the search fails, it is continued in the superclass of that class, and so forth, up to the system class, `Object`, which has no superclass. `Object` is the root of the class derivation tree on which every class is a node. If no method is found anywhere in that chain, an error occurs. It is important to remember that this method search is dynamic —it takes place when the message is sent. Smalltalk does not, under any circumstances, bind messages to methods statically.

The only type checking in Smalltalk is dynamic, and the only type error occurs when a message is sent to an object that has no matching method, either locally or through inheritance. This is a different concept of type checking than that of most other languages. Smalltalk type checking has the simple goal of ensuring that a message matches some method.

Smalltalk variables are not typed; any name can be bound to any object. As a direct result, Smalltalk supports dynamic polymorphism. All Smalltalk code is generic in the sense that the types of the variables are irrelevant, as long as they are consistent. The meaning of an operation (method or operator) on a variable is determined by the class of the object to which the variable is currently bound.

The point of this discussion is that as long as the objects referenced in an expression have methods for the messages of the expression, the types of the objects are irrelevant. This means that no code is tied to a particular type.

12.4.1.4 Evaluation of Smalltalk

Smalltalk is a small language, although the Smalltalk system is large. The syntax of the language is simple and highly regular. It is a good example of the power that can be provided by a small language if that language is built around a simple but powerful concept. In the case of Smalltalk, that concept is that all programming can be done employing only a class hierarchy built using inheritance, objects, and message passing.

In comparison with conventional compiled imperative-language programs, equivalent Smalltalk programs are significantly slower. Although it is

theoretically interesting that array indexing and loops can be provided within the message-passing model, efficiency is an important factor in the evaluation of programming languages. Therefore, efficiency will clearly be an issue in most discussions of the practical applicability of Smalltalk.

Smalltalk's dynamic binding allows type errors to go undetected until run time. A program can be written that includes messages to nonexistent methods and it will not be detected until the messages are sent, which causes a great deal more error repair later in the development than would occur in a static-typed language. However, in practice type errors are not a serious problem with Smalltalk programs.

Overall, the design of Smalltalk consistently came down on the side of language elegance and strict adherence to the principles of object-oriented programming support, often without regard for practical matters, in particular execution efficiency. This is most obvious in the exclusive use of objects and the typeless variables.

The Smalltalk user interface has had an important impact on computing: The integrated use of windows, mouse-pointing devices, and pop-up and pull-down menus, all of which first appeared in Smalltalk, dominate contemporary software systems.

Perhaps the greatest impact of Smalltalk is the advancement of object--oriented programming, now the most widely used design and coding methodology.

12.4.2 C++

Chapter 2 describes how C++ evolved from C and SIMULA 67, with the design goal of support for object-oriented programming while retaining nearly complete backward compatibility with C. C++ classes, as they are used to support abstract data types, are discussed in Chapter 11. C++ support for the other essentials of object-oriented programming is explored in this section. The whole collection of details of C++ classes, inheritance, and dynamic binding is large and complex. This section discusses only the most

important among these topics, specifically, those directly related to the design issues described in Section 12.3.

C++ was the first widely used object-oriented programming language and is still among the most popular. So, naturally, it is the one with which other languages are often compared. For both of these reasons, our coverage of C++ here is more detailed than that of the other example languages discussed in this chapter.

12.4.2.1 General Characteristics

To maintain backward compatibility with C, C++ retains the type system of C and adds classes to it. Therefore, C++ has both traditional imperative--language types and the class structure of an object-oriented language. It supports methods, as well as functions that are not related to specific classes. This makes it a hybrid language, supporting both procedural programming and object-oriented programming.

The objects of C++ can be static, stack dynamic, or heap dynamic. Explicit deallocation using the **`delete`** operator is required for heap-dynamic objects, because C++ does not include implicit storage reclamation.

Many class definitions include a destructor method, which is implicitly called when an object of the class ceases to exist. The destructor is used to deallocate heap-allocated memory that is referenced by data members. It may also be used to record part or all of the state of the object just before it dies, usually for debugging purposes.

12.4.2.2 Inheritance

A C++ class can be derived from an existing class, which is then its parent, or base, class. Unlike Smalltalk and most other languages that support object--oriented programming, a C++ class can also be stand-alone, without a superclass. In the definition of a derived class, the name of the derived class has the name of the base class attached with a colon (:), as in the following

syntactic form:

- **`class`** derived_class_name `:` base_class_name `{ ... }`

The data defined in a class definition are called *data members* of that class, and the functions defined in a class definition are called *member functions* of that class (member functions in other languages are usually called methods). Some or all of the members of the base class may be inherited by the derived class, which can also add new members and modify inherited member functions.

All C++ objects must be initialized before they are used. Therefore, all C++ classes include at least one constructor method that initializes the data members of the new object. Constructor methods are implicitly called when an object is created. If any of the data members are pointers to heap-allocated data, the constructor allocates that storage.

If a class is derived from another class, the inherited data members must be initialized when the derived class object is created. To do this, the base class constructor is implicitly called. When initialization data must be furnished to the base class constructor, it is given in the call to the derived object - constructor. In general, this is done with the following construct:

- subclass`(`subclass parameters`):` base_class`(`superclass parameters`) {`
- `. . .`
- `}`

interview

On Paradigms and Better Programming

BJARNE STROUSTRUP

Bjarne Stroustrup is the designer and original implementer of C++ and the author of A Tour of C++, Programming: Principles and Practice Using C++, The C++ Programming Language, The Design and Evolution of C++, and many other publications. His research interests include distributed systems, design, programming techniques, software development tools, and programming languages. He is actively involved in the ANSI/ISO standardization of C++. Dr. Stroustrup is a managing director in the technology division of Morgan Stanley in New York City, a Visiting Professor in Computer Science at Columbia University, and a Distinguished Research Professor in Computer Science at Texas A&M University. He is a member of the National Academy of Engineering, an ACM Fellow, and an IEEE Fellow. In 1993, Stroustrup received the ACM Grace Murray Hopper Award “for his early work laying the foundations for the C++ programming language. Based on the foundations and Dr. Stroustrup’s continuing efforts, C++ has become one of the most influential programming languages in the history of computing.”

(year of interview: 2002)

PROGRAMMING PARADIGMS

Your thoughts on the object-oriented paradigm: Its pluses and minuses. Let me first say what I mean by OOP—too many people think that "object-oriented" is simply a synonym for "good." If so, there would be no need for other paradigms. The key to OO is the use of class hierarchies providing polymorphic behavior through some rough equivalent of virtual functions. For proper OO, it is important to avoid directly accessing the data in such a hierarchy and to use only a well-designed functional interface.

In addition to its well-documented strengths, object-oriented programming also has obvious weaknesses. In particular, not every concept naturally fits into a class hierarchy, and the mechanisms supporting object-oriented programming can impose significant overheads compared to alternatives. For many simple abstractions, classes that do not rely on hierarchies and run-time binding provide a simpler and more efficient alternative. Furthermore, where no run-time resolution is needed, generic programming relying on (compile-time) parametric polymorphism is a better behaved and more efficient approach.

So, C++: Is it OO or other? C++ supports several paradigms—including OOP, generic programming, and procedural programming—and combinations of these paradigms define multiparadigm programming as supporting more than one programming style ("paradigm") and combinations of those styles.

Do you have a mini-example of multiparadigm programming? Consider this variant of the classic "collection of shapes" examples (originating from the early days of the first language to support object-oriented programming: Simula 67):

```
void draw_all(const vector<Shape*>& vs)
{
   for (int i = 0; i<vs.size(); ++i)
       vs[i]->draw();
}
```

Here, I use the generic container `vector` together with the polymorphic type

`Shape`. The `vector` provides static type safety and optimal run-time performance. The `Shape` provides the ability to handle a `Shape` (i.e., any object of a class derived from `Shape`) without recompilation.

We can easily generalize this to any container that meets the C++ standard library requirements:

```
template<class C>
       void draw_all(const C& c)
{
    typedef typename C::
       const_iterator CI;
    for (CI p = c.begin();
       p!=c.end(); ++p)
       (*p)->draw();
}
```

Using iterators allows us to apply this `draw_all ()` to containers that do not support subscripts, such as a standard library list:

```
vector<Shape*> vs;
list<Shape*> ls;
// . . .
draw_all(vs);
draw_all(ls);
```

We can even generalize this further to handle any sequence of elements defined by a pair of iterators:

```
template<class Iterator> void draw_all(Iterator b, Iterator e)
{
    for_each(b,e,mem_fun(&Shape::draw));
}
```

To simplify the implementation, I used the standard library algorithm `for_each`.

We might call this last version of `draw_all()` for a standard library list and an array:

```
list<Shape*> ls;
Shape* as[100];
// . . .
```

```
draw_all(ls.begin(),ls.end());
draw_all(as,as+100);
```

SELECTING THE "RIGHT" LANGUAGE FOR THE JOB

How useful is it to have this background in numerous paradigms? Or would it be better to invest time in becoming even more familiar with OO languages rather than learning these other paradigms? It is essential for anyone who wants to be considered a professional in the areas of software to know several languages and several programming paradigms. Currently, C++ is the best language for multiparadigm programming and a good language for learning various forms of programming. However, it's not a good idea to know just C++, let alone to know just a single-paradigm language. That would be a bit like being colorblind or monoglot: You would hardly know what you were missing. Much of the inspiration to good programming comes from having learned and appreciated several programming styles and seen how they can be used in different languages.

Furthermore, I consider programming of any nontrivial program a job for professionals with a solid and broad education, rather than for people with a hurried and narrow "training."

If no constructor is included by the developer in a class definition, the compiler includes a trivial constructor. This default constructor calls the constructor of the base class, if there is a base class.

Class members can be private, protected, or public. Private members are accessible only by member functions and friends of the class. Standalone functions, member functions, and classes can be declared to be friends of a class and thereby be given access to its private members. Public members are visible everywhere. Protected members are like private members, except in derived classes, whose access is described next. Derived classes can modify accessibility for their inherited members. The complete syntactic form of a derived class is as follows:

- **`class`** derived_class_name : derivation_mode base_class_name

  {data member and member function declarations};

The derivation_mode can be either **`public`** or **`private`**.9 (Do not confuse public and private derivation with public and private members.) The public and protected members of a base class are also public and protected, respectively, in a public-derived class. In a private-derived class, both the public and protected members of the base class are private. So, in a class hierarchy, a private-derived class cuts off access to all members of all ancestor classes to all successor classes. Private members of a base class are inherited by a derived class, but they are not visible to the members of that derived class and are therefore of no use there. Private derivations provide the possibility that a subclass can have members with different access than the same members in the parent class. Consider the following example:

9. It can also be **`protected`**, but that option is not discussed here.

```
class base_class {
  private:
    int a;
    float  x;
  protected:
    int b;
    float y;
  public:
    int c;
    float z;
};
 class subclass_1 : public base_class {. . .};
 class subclass_2 : private base_class {. . .};
```

In `subclass_1`, `b` and `y` are protected, and `c` and `z` are public. In `subclass_2`, `b`, `y`, `c`, and `z` are private. No derived class of `subclass_2` can have members with access to any member of `base_class`. The data members `a` and `x` in `base_class` are not accessible in either `subclass_1` or `subclass_2`.

Note that private-derived subclasses cannot be subtypes. For example, if the base class has a public data member, under private derivation that data member would be private in the subclass. Therefore, if an object of the subclass were substituted for an object of the base class, accesses to that data

member would be illegal on the subclass object. However, public-derived subclasses can be and usually are subtypes.

Under private class derivation, no member of the parent class is implicitly visible to the instances of the derived class. Any member that must be made visible must be reexported in the derived class. This reexportation in effect exempts a member from being hidden even though the derivation was private. For example, consider the following class definition:

```
class subclass_3 : private base_class {
  base_class :: c;
  . . .
}
```

Now, instances of `subclass_3` can access `c`. As far as `c` is concerned, it is as if the derivation had been public. The double colon (`::`) in this class definition is a scope resolution operator. It specifies the class where its following entity is defined.

The example in the following paragraphs illustrates the purpose and use of private derivation.

Consider the following example of C++ inheritance, in which a general linked-list class is defined and then used to define two useful subclasses:

```
class single_linked_list {
  private:
    class node {
      public:
        node *link;
        int contents;
    };
    node *head;
  public:
    single_linked_list() {head = 0};
    void  insert_at_head(int);
    void  insert_at_tail(int);
    int  remove_at_head();
    int  empty();
};
```

The nested class, `node`, defines a cell of the linked list to consist of an integer

variable and a pointer to a `node` object. The `node` class is in the private clause, which hides it from all other classes. Its members are public, however, so they are visible to the nesting class, `single_linked_list`. If they were private, `node` would need to declare the nesting class to be a friend to make them visible in the nesting class. Note that nested classes have no special access to members of the nesting class. Only static data members of the nesting class are visible to methods of the nested class.10

10. A class can also be defined in a method of a nesting class. The scope rules of such classes are the same as those for classes nested directly in other classes, even for the local variables declared in the method in which they are defined.

The enclosing class, `single_linked_list`, has just a single data member, a pointer to act as the list's header. It contains a constructor function, which sets `head` to the null pointer value. The four member functions allow nodes to be inserted at either end of a list object, nodes to be removed from one end of a list, and lists to be tested for empty.

The following definitions provide stack and queue classes, both based on the `single_linked_list` class:

```
class stack : public single_linked_list {
  public:
    stack() {}
    void push(int value) {
      insert_at_head(value);
    }
    int pop() {
      return remove_at_head();
    }
};
class queue : public single_linked_list {
  public:
    queue() {}
    void enqueue(int value) {
      insert_at_tail(value);
    }
    int dequeue() {
      remove_at_head();
    }
};
```

Note that objects of both the `stack` and `queue` subclasses can access the `empty` function defined in the base class, `single_linked_list` (because it is a public derivation). Both subclasses define constructor functions that do nothing. When an object of a subclass is created, the proper constructor in the subclass is implicitly called. Then, any applicable constructor in the base class is called. So, in our example, when an object of type `stack` is created, the constructor in `single_linked_list` is called, which does the necessary initialization. Then the `stack` constructor is called, which does nothing.

The classes `stack` and `queue` both suffer from the same serious problem: Clients of both can access all of the public members of the parent class, `single_linked_list`. A client of a `stack` object could call `insert_at_tail`, thereby destroying the integrity of its stack. Likewise, a client of a `queue` object could call `insert_at_head`. These unwanted accesses are allowed because both `stack` and `queue` are subtypes of `single_linked_list`. Public derivation is used when one wants the subclass to inherit the entire interface of the base class. The alternative is to use a derivation in which the subclass inherits only the implementation of the base class. Our two example derived classes can be written to make them not subtypes of their parent class by using **`private`**, rather than **`public`**, derivation.11 Then, both will also need to reexport `empty`, because it will become hidden to their instances. This situation illustrates the motivation for the private-derivation option. The new definitions of the stack and queue types, named `stack_2` and `queue_2`, are shown in the following:

11. They would not be subtypes because the public members of the parent class can be seen in a client, but not in a client of the subclass, where those members are private.

```
class stack_2 : private single_linked_list {
  public:
    stack_2() {}
    void push(int value) {
      single_linked_list :: insert_at_head(value);
    }
    int pop() {
      return single_linked_list :: remove_at_head();
    }
    single_linked_list:: empty();
};
```

```
class queue_2 : private single_linked_list {
  public:
    queue_2() {}
    void enqueue(int value) {
      single_linked_list :: insert_at_tail(value);
    }
    int dequeue() {
      single_linked_list :: remove_at_head();
    }
    single_linked_list:: empty();
};
```

These two classes use reexportation to allow access to base class methods for clients. This was not necessary when public derivation was used.

The two versions of stack and queue illustrate the difference between subtypes and derived types that are not subtypes. The linked list is a generalization of both stacks and queues, because both can be implemented as linked lists. So, it is natural to inherit from a linked-list class to define stack and queue classes. However, neither is a subtype of the linked-list class, because both make the public members of the parent class private, which makes them inaccessible to clients.

One of the reasons friends are necessary is that sometimes a subprogram must be written that can access the members of two different classes. For example, suppose a program uses a class for vectors and one for matrices, and a subprogram is needed to multiply a matrix object by a vector object. In C++, the multiply function can be made a friend of both classes.

As previously stated, C++ provides multiple inheritance. As an example, suppose we wanted a class for drawing that needed the behavior of a class written for drawing figures and the methods of the new class needed to run in a separate thread. We might define the following:

```
class Thread { . . . };
class Drawing { . . . };
class DrawThread : public Thread, public Drawing { . . . };
```

Class `DrawThread` inherits all of the members of both `Thread` and `Drawing`. If both `Thread` and `Drawing` happen to include members with the same name, they can be unambiguously referenced in objects of class `DrawThread` by

using the scope resolution operator (::). This example of multiple inheritance is shown in Figure 12.5.

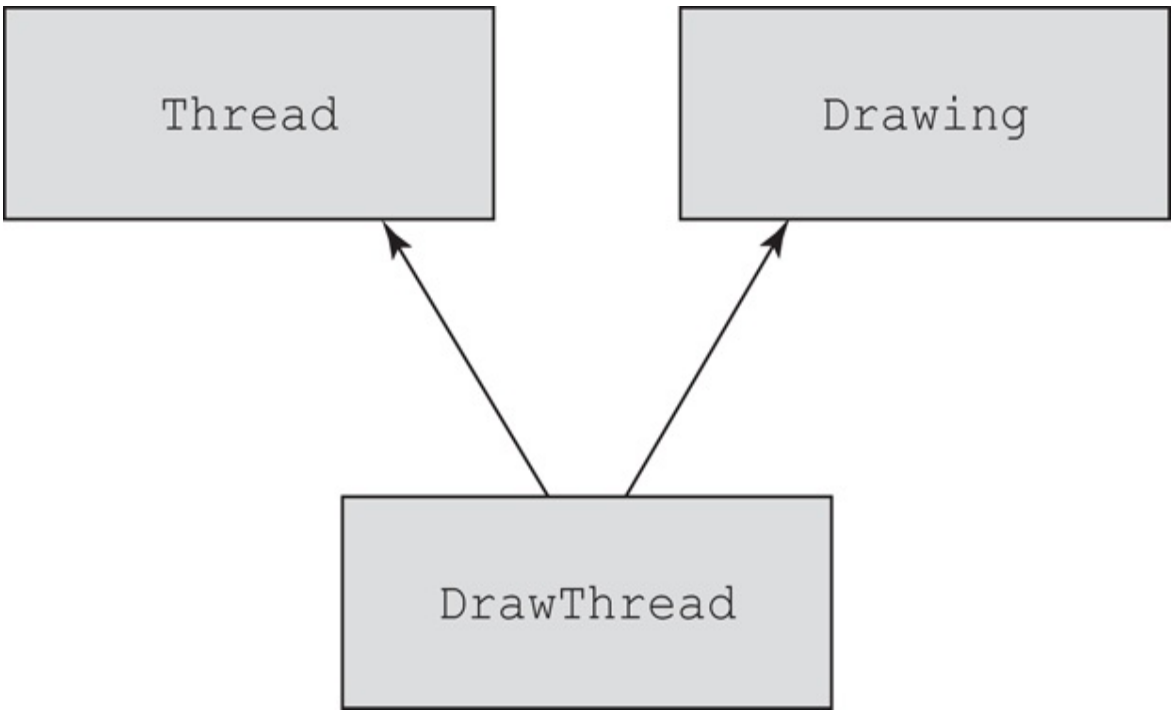

Figure 12.5 Multiple inheritance

Some issues with the C++ implementation of multiple inheritance are discussed in Section 12.5.

Overriding methods12 in C++ must have exactly the same parameter profile as the overridden method. If there is any difference in the parameter profiles, the method in the subclass is considered a new method that is unrelated to the method with the same name in the ancestor class. The return type of the overriding method either must be the same as that of the overridden method or must be a publicly derived type of the return type of the overridden method.

12. Recall that an overriding method is one that is defined in the derived class to replace a virtual method inherited from an ancestor class. Calls to an

overriding method must be dynamically bound.

12.4.2.3 Dynamic Binding

All of the member functions we have defined thus far are statically bound; that is, a call to one of them is statically bound to a function definition. A C++ object could be manipulated through a value variable, rather than a pointer or a reference. (Such an object would be static or stack dynamic.) However, in that case, the object's type is known and static, so dynamic binding is not needed. On the other hand, a pointer variable that has the type of a base class can be used to point to any heap-dynamic object of any class publicly derived from that base class, making it a polymorphic variable. Publicly derived subclasses are subtypes if none of the members of the base class are private. Privately derived subclasses are never subtypes. A pointer to a base class cannot be used to reference a method in a subclass that is not a subtype.

C++ does not allow value variables (as opposed to pointers or references) to be polymorphic. When a polymorphic variable is used to call a member function overridden in one of the derived classes, the call must be dynamically bound to the correct member function definition.

Consider the situation of having a base class named `Shape`, along with a collection of derived classes for different kinds of shapes, such as circles, rectangles, and so forth. If these shapes need to be displayed, then the displaying member function, `draw`, must be unique for each descendant, or kind of shape. These versions of `draw` must be defined to be virtual. When a call to `draw` is made with a pointer to the base class of the derived classes, that call must be dynamically bound to the member function of the correct derived class. The following example has the skeletal definitions for the example situation just described:

```
class Shape {
  public:
    virtual void  draw() = 0;
  . . .
};
```

```
class Circle : public Shape {
  public:
    void draw() { . . . }
  . . .
};
class Rectangle : public Shape {
  public:
    void draw() { . . . }
  . . .
};
```

Given these definitions, the following code has examples of both statically and dynamically bound calls:

```
Circle* circ = new Circle;
Rectangle* rect = new Rectangle;
Shape* ptr_shape;
ptr_shape = circ;          // Now ptr_shape points to a
                           //  Circle object
ptr_shape->draw();      // Dynamically bound to the draw
                           //  in the Circle class
rect->draw();              // Statically bound to the draw
                           //  in the Rectangle class
```

This situation is shown in Figure 12.6.

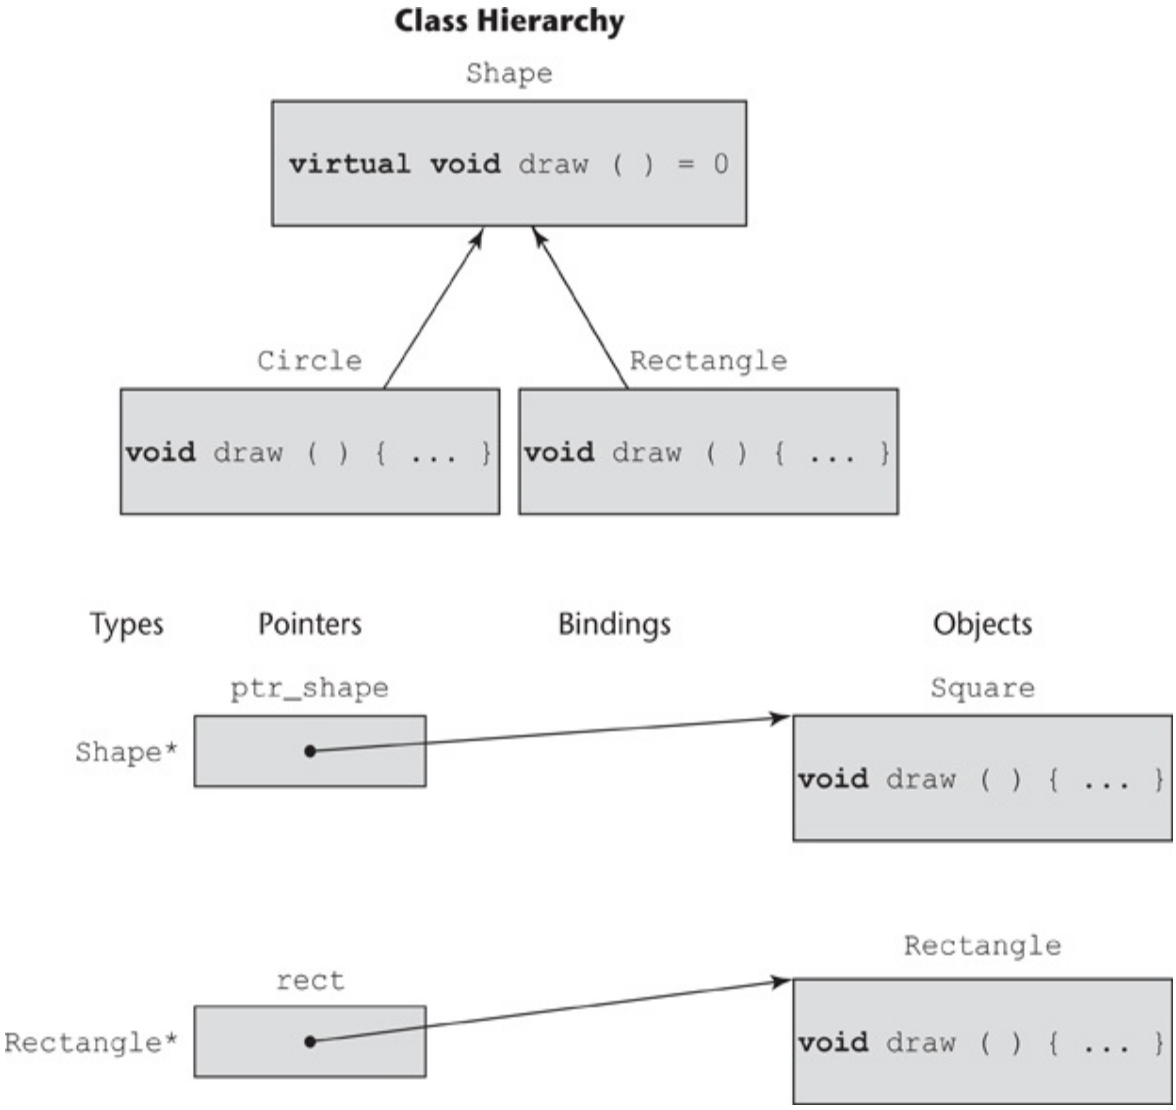

Figure 12.6 Dynamic binding

Figure 12.6 Full Alternative Text

Notice that the `draw` function in the definition of the base class `shape` is set to 0. This peculiar syntax is used to indicate that this member function is a **pure virtual function**, meaning that it has no body and it cannot be called. It must be redefined in derived classes if they call the function. The purpose of a pure virtual function is to provide the interface of a function without giving any of its implementation. Pure virtual functions are usually defined when an actual member function in the base class would not be useful. Recall that in

Section 12.2.3, a base class `Building` was discussed, and each subclass described some particular kind of building. Each subclass had a `draw` method but none of these would be useful in the base class. So, `draw` would be a pure virtual function in the `Building` class.

Any class that includes a pure virtual function is an **abstract class**. In C++, an abstract class is not marked with a reserved word. An abstract class can include completely defined methods. Because of the presence of one or more virtual functions, it is illegal to instantiate an abstract class. In a strict sense, an abstract class is one that is used only to represent the characteristics of a type. C++ provides abstract classes to model these truly abstract classes. If a subclass of an abstract class does not redefine a pure virtual function of its parent class, that function remains as a pure virtual function in the subclass and the subclass is also an abstract class.

Abstract classes and inheritance together support a powerful technique for software development. They allow types to be hierarchically defined so that related types can be subclasses of truly abstract types that define their common abstract characteristics.

Dynamic binding allows the code that uses members like `draw` to be written before all or even any of the versions of `draw` are written. New derived classes could be added years later, without requiring any change to the code that uses such dynamically bound members. This is a highly useful feature of object-oriented languages.

Reference assignments for stack-dynamic objects are different from pointer assignments for heap-dynamic objects. For example, consider the following code, which uses the same class hierarchy as the last example:

```
Circle circ;     // Allocate a Circle object on the stack
Rectangle rect;  // Allocate a Rectangle object on
                 //  the stack
rect = circ;     // Copies the data member values from
                 //  the Circle object
rect.draw();     // Calls the draw from the Rectangle
                 //  object
```

In the assignment `rect = circ`, the member data from the object referenced

by `circ` would be assigned to the data members of the object referenced by `rect`, but `rect` would still reference the `Rectangle` object. Therefore, the call to `draw` through the object referenced by `rect` would be that of the `Rectangle` class. If `rect` and `circ` were pointers to heap-dynamic objects, the same assignment would be a pointer assignment, which would make `rect` point to the `Circle` object, and a call to `draw` through `rect` would be bound dynamically to the `draw` in the `Circle` object.

12.4.2.4 Evaluation

It is natural to compare the object-oriented features of C++ with those of Smalltalk. The inheritance of C++ is more intricate than that of Smalltalk in terms of access control. By using both the access controls within the class definition and the derivation access controls, and also the possibility of friend functions and friend classes, the C++ programmer has highly detailed control over access to class members. Although C++ provides multiple inheritance and Smalltalk does not, there are many who feel that is not an advantage for C++. The downsides of multiple inheritance weigh heavily against its value. In fact, C++ is the only language discussed in this chapter that supports multiple inheritance. On the other hand, languages that provide alternatives to multiple inheritance, such as Java and C#, clearly have an advantage over Smalltalk in that area.

In C++, the programmer can specify whether static binding or dynamic binding is to be used. Because static binding is faster, this is an advantage for those situations where dynamic binding is not necessary. Furthermore, even the dynamic binding in C++ is fast when compared with that of Smalltalk. Binding a virtual member function call in C++ to a function definition has a fixed cost, regardless of how distant in the inheritance hierarchy the definition appears. Calls to virtual functions require only five more memory references than statically bound calls (Stroustrup, 1988). In Smalltalk, however, messages are always dynamically bound to methods, and the farther away in the inheritance hierarchy the correct method is, the longer it takes. The disadvantage of allowing the user to decide which bindings are static and which are dynamic is that the original design must include these decisions, which may have to be changed later.

The static type checking of C++ is an advantage over Smalltalk, in which all type checking is dynamic. A Smalltalk program can be written with messages to nonexistent methods, which are not discovered until the program is executed. A C++ compiler finds such errors. Compiler-detected errors are less expensive to repair than those found in testing.

Smalltalk is essentially typeless, meaning that all code is effectively generic. This provides a great deal of flexibility, but static type checking is sacrificed. C++ provides generic classes through its template facility (as described in Chapter 11), which retains the benefits of static type checking.

The primary advantage of Smalltalk lies in the elegance and simplicity of the language, which results from the single philosophy of its design. It is purely and completely devoted to the object-oriented paradigm, devoid of compromises necessitated by the whims of an entrenched user base. C++, on the other hand, is a large and complex language with no single philosophy as its foundation, except to support object-oriented programming and include the C user base. One of its most significant goals was to preserve the efficiency and flavor of C while providing the advantages of object-oriented programming. Some people feel that the features of this language do not always fit well together and that at least some of the complexity is unnecessary.

According to Chambers and Ungar (1991), Smalltalk ran a particular set of small C-style benchmarks at only 10 percent of the speed of optimized C. C++ programs require only slightly more time than equivalent C programs (Stroustrup, 1988). Given the great efficiency gap between Smalltalk and C++, it is little wonder that the commercial use of C++ is far more widespread than that of Smalltalk. There are other factors in this difference, but efficiency is clearly a strong argument in favor of C++. Of course, all of the compiled languages that support object-oriented programming run approximately 10 times faster than Smalltalk.

12.4.3 Java

Because Java’s design of classes, inheritance, and methods is similar to that

of C++, in this section we focus only on those areas in which Java differs from C++.

12.4.3.1 General Characteristics

As with C++, Java supports both objects and nonobject data. However, in Java, only values of the primitive scalar types (Boolean, character, and the numeric types) are not objects. Java's enumerations and arrays are objects. The reason Java has nonobjects is efficiency.

In Java 5.0+, primitive values are implicitly coerced when they are put in object context. This coercion converts the primitive value to an object of the wrapper class of the primitive value's type. For example, putting an **`int`** value or variable into object context causes the creation of an `Integer` object with the value of the **`int`** primitive. This coercion is called **boxing**.

Whereas C++ classes can be defined to have no parent, that is not possible in Java. All Java classes must be subclasses of the root class, `Object`, or some class that is a descendant of `Object`. One advantage of this is that some commonly needed methods, such as `toString` and `equals`, can be defined in `Object` and inherited and used by all other classes.

All Java objects are explicit heap dynamic. Most are allocated with the **`new`** operator, but there is no explicit deallocation operator. Garbage collection is used for storage reclamation. Like many other language features, although garbage collection avoids some serious problems, such as dangling pointers, it can cause other problems. One such difficulty arises because the garbage collector deallocates, or reclaims the storage occupied by an object, but it does no more. For example, if an object has access to some resource other than heap memory, such as a file or a lock on a shared resource, the garbage collector does not reclaim these. For these situations, Java allows the inclusion of a special method, **`finalize`**, which is related to a C++ destructor function.

A **`finalize`** method is implicitly called when the garbage collector is about to reclaim the storage occupied by the object. The problem with **`finalize`** is

that the time it (and the garbage collector) will run cannot be forced or even predicted. The alternative to using **`finalize`** to reclaim resources held by an object about to be garbage collected is to include a method that does the reclamation. The only problem with this is that all clients of the objects must be aware of this method and remember to call it.

12.4.3.2 Inheritance

In Java, a method can be defined to be **`final`**, which means that it cannot be overridden in any descendant class. When the **`final`** reserved word is specified on a class definition, it means the class cannot be subclassed. All of the methods in a final class are implicitly final, which means that the bindings of method calls to the methods of the class are statically bound.

The advantage of defining a class to be final is that no changes to the class are allowed. For example, `String` is a final class and because of that any method that receives a `String` reference in a parameter can depend on the stability of the meaning of `String`'s methods. The disadvantage is that defining a class to be final disallows reuses that require even minor modifications.

Java includes the annotation `@Override`, which informs the compiler to check to determine whether the following method overrides a method in an ancestor class. If it does not, the compiler issues an error message.

Like C++, Java requires that parent class constructor be called before the subclass constructor is called. If parameters are to be passed to the parent class constructor, that constructor must be explicitly called, as in the following example:

```
super(100, true);
```

If there is no explicit call to the parent class constructor, the compiler inserts a call to the zero-parameter constructor in the parent class.

Java does not support the private derivations of C++. One can surmise that the Java designers believed that subclasses should be subtypes, which they

are not when private derivations are supported. Thus, they did not include them. So, Java's subclasses can be subtypes.

Early versions of Java included a collection, `Vector`, which included a long list of methods for manipulating data in a collection construct. These versions of Java also included a subclass of `Vector`, `Stack`, which added methods for push and pop operations. Unfortunately, because Java does not have private derivation, all of the methods of `Vector` were also visible in the `Stack` class, which made `Stack` objects liable to a variety of operations that could invalidate those objects.

Java directly supports only single inheritance. However, it includes a kind of abstract class, called an **interface**, which provides partial support for multiple inheritance. An interface definition is similar to a class definition, except that it can contain only named constants and method declarations (not definitions). It cannot contain constructors, nonabstract methods, or variable declarations. So, an interface is no more than what its name indicates—it defines only the specification of a class. (Recall that a C++ abstract class can have instance variables and all but one of the methods can be completely defined.) A class does not inherit an interface; it implements it. In fact, a class can implement any number of interfaces. To implement an interface, the class must implement all of the methods whose specifications (but not bodies) appear in the interface definition.

An interface can be used to simulate multiple inheritance. A class can be derived from a class and implement an interface, with the interface taking the place of a second parent class. This is sometimes called **mixin inheritance,** because the constants and methods of the interface are mixed in with the methods and data inherited from the superclass, as well as any new data and/or methods defined in the subclass.

One more interesting capability of interfaces is that they provide another kind of polymorphism. This is because interfaces can be treated as types. For example, a method can specify a formal parameter that is an interface. Such a formal parameter can accept an actual parameter of any class that implements the interface, making the method polymorphic.

A nonparameter variable also can be declared to be of the type of an

interface. Such a variable can reference any object of any class that implements the interface.

One of the problems with multiple inheritance occurs when a class is derived from two parent classes and both define a public method with the same name and protocol. This problem is avoided with interfaces. Although a class that implements an interface must provide definitions for all of the methods specified in the interface, if the class and the interface both include methods with the same name and protocol, the class need not reimplement that method. So, the method name conflicts that can occur with multiple inheritance cannot occur with single inheritance and interfaces. Furthermore, variable name conflicts are completely avoided because interfaces cannot define variables.

An interface is not a replacement for multiple inheritance, because in multiple inheritance there is code reuse, while interfaces provide no code reuse. This is an important difference, because code reuse is one of the primary benefits of inheritance. Java provides one way to partially avoid this deficiency. One of the implemented interfaces could be replaced by an abstract class, which could include code that could be inherited, thereby providing some code reuse.

One problem with interfaces being a replacement for multiple inheritance is the following: If a class attempts to implement two interfaces and both define methods that have the same name and protocol, there is no way to implement both in the class.

As an example of an interface, consider the `sort` method of the standard Java class, `Array`. Any class that uses this method must provide an implementation of a method to compare the elements to be sorted. The generic `Comparable` interface provides the protocol for this comparing method, which is named `compareTo`. The code for the `Comparable` interface is as follows:

```
public interface Comparable <T> {
    public int compareTo(T b);
}
```

The `compareTo` method must return a negative integer if the object through which it is called belongs before the parameter object, zero if they are equal,

and a positive integer if the parameter belongs before the object through which `compareTo` was called. A class that implements the `Comparable` interface can sort the contents of any array of objects of the generic type, as long as the implemented `compareTo` method for the generic type is implemented and provides the appropriate value. Interfaces have become a common substitute for multiple inheritance. Some form of interfaces are now part of C#, Swift, Ruby, and Ada.

In addition to interfaces, Java also supports abstract classes, similar to those of C++. The abstract methods of a Java abstract class are represented as just the method's header, which includes the **`abstract`** reserved word. The abstract class is also marked **`abstract`**. Of course, abstract classes cannot be instantiated.

Chapter 14 illustrates the use of interfaces in Java event handling.

12.4.3.3 Dynamic Binding

In C++, a method must be defined as virtual to allow dynamic binding. In Java, all method calls are dynamically bound unless the called method has been defined as **`final`**, in which case it cannot be overridden and all bindings are static. Static binding is also used if the method is **`static`** or **`private`**, both of which disallow overriding.

12.4.3.4 Nested Classes

Java has several varieties of nested classes, all of which have the advantage of being hidden from all classes in their package, except for the nesting class. Nonstatic classes that are nested directly in another class are called **inner classes**. Each instance of an inner class must have an implicit pointer to the instance of its nesting class to which it belongs. This gives the methods of the nested class access to all of the members of the nesting class, including the private members. Static nested classes do not have this pointer, so they cannot access members of the nesting class. Therefore, static nested classes in

Java are like the nested classes of C++.

Though it seems odd in a static-scoped language, the members of the inner class, even the private members, are accessible in the outer class. Such references must include the variable that references the inner class object. For example, suppose the outer class creates an instance of the inner class with the following statement:

```
myInner = this.new Inner();
```

Then, if the inner class defines a variable named `sum`, it can be referenced in the outer class as `myInner.sum`.

An instance of a nested class can only exist within an instance of its nesting class. Nested classes can also be anonymous. Anonymous nested classes have complex syntax but are really only an abbreviated way to define a class that is used from just one location. An example of an anonymous nested class appears in Chapter 14.

A **local nested class** is defined in a method of its nesting class. Local nested classes are never defined with an access specifier (**`private`** or **`public`**). Their scope is always limited to their nesting class. A method in a local nested class can access the variables defined in its nesting class and the **`final`** variables defined in the method in which the local nested class is defined. The members of a local nested class are visible only in the method in which the local nested class is defined.

12.4.3.5 Evaluation

Java's design for supporting object-oriented programming is similar to that of C++, but it employs more consistent adherence to object-oriented principles. Java does not allow parentless classes and uses dynamic binding as the "normal" way to bind method calls to method definitions. This, of course, increases execution time slightly over languages in which many method bindings are static. At the time this design decision was made, however, most Java programs were interpreted, so interpretation time made the extra binding time insignificant. Access controls for the contents of a class definition are

rather simple when compared with the jungle of access controls of C++, ranging from derivation controls to friend functions. Finally, Java uses interfaces to provide a form of support for multiple inheritance, which does not have all of the drawbacks of actual multiple inheritance.

12.4.4 C#

C#'s support for object-oriented programming is similar to that of Java.

12.4.4.1 General Characteristics

C# includes both classes and structs, with the classes being very similar to Java's classes and the structs being somewhat less powerful constructs. One important difference is that structs are value types; that is, they are stack dynamic. This could cause the problem of object slicing, but this is prevented by the restriction that structs cannot be subclassed. More details of how C# structs differ from its classes appeared in Chapter 11.

12.4.4.2 Inheritance

C# uses the syntax of C++ for defining classes. For example,

```
public class  NewClass : ParentClass { . . . }
```

A method inherited from the parent class can be replaced in the derived class by marking its definition in the subclass with **new**. The **new** method hides the method of the same name in the parent class to normal access. However, the parent class version can still be called by prefixing the call with **base**. For example,

```
base.Draw();
```

As with Java, subclasses can be subtypes. C#'s support for interfaces is the same as that of Java. It does not support multiple inheritance.

12.4.4.3 Dynamic Binding

To allow dynamic binding of method calls to methods in C#, both the base method and its corresponding methods in derived classes must be specially marked. The base class method must be marked with **`virtual`**, as in C++. To make clear the intent of a method in a subclass that has the same name and protocol as a virtual method in an ancestor class, C# requires that such methods be marked **`override`** if they are to override the parent class virtual method.13 For example, the C# version of the C++ `Shape` class that appears in Section 12.4.2.3 is as follows:

13. Recall that this can be specified in Java with the annotation `@Override`.

```
public class Shape {
  public virtual void Draw() { . . . }
  . . .
}
public class Circle : Shape {
  public override void Draw() { . . . }
  . . .
}
public class Rectangle : Shape {
  public override void Draw() { . . . }
  . . .
}
public class Square : Rectangle {
  public override void Draw() { . . . }
  . . .
}
```

C# includes abstract methods similar to those of C++, except that they are specified with different syntax. For example, the following is a C# abstract method:

```
abstract public void Draw();
```

A class that includes at least one abstract method is an abstract class, and every abstract class must be marked **`abstract`**. Abstract classes cannot be instantiated. It follows that any subclass of an abstract class that will be instantiated must implement all abstract methods that it inherits.

As with Java, all C# classes are ultimately derived from a single root class, `Object`. The `Object` class defines a collection of methods, including `ToString`, `Finalize`, and `Equals`, which are inherited by all C# types.

12.4.4.4 Nested Classes

A C# class that is directly nested in a class behaves like a Java static nested class (which is like a nested class in C++). Like C++, C# does not support nested classes that behave like the nonstatic nested classes of Java.

12.4.4.5 Evaluation

Because C# is a recently designed C-based object-oriented language, one should expect that its designers learned from their predecessors and duplicated the successes of the past and remedied some of the problems. One result of this, coupled with the few problems with Java, is that the differences between C#'s support for object-oriented programming and that of Java are relatively minor. The availability of structs in C#, which Java does not have, can be considered an improvement. Like that of Java, C#'s support for object-oriented programming is simpler than that of C++, which many consider an improvement.

12.4.5 Ruby

As stated previously, Ruby is a pure object-oriented programming language in the sense of Smalltalk. Virtually everything in the language is an object and all computation is accomplished through message passing. Although programs have expressions that use infix operators and therefore have the same appearance as expressions in languages like Java, those expressions actually are evaluated through message passing. As is the case with Smalltalk, when one writes `a + b`, it is evaluated by sending the message `+` to the object referenced by `a`, passing a reference to the object `b` as a parameter. In other words, `a + b` is implemented as `a.+ b`.

12.4.5.1 General Characteristics

Ruby class definitions differ from those of languages such as C++ and Java in that they are executable. Because of this, they are allowed to remain open during execution. A program can add members to a class any number of times, simply by providing secondary definitions of the class that include the new members. During execution, the current definition of a class is the union of all definitions of the class that have been executed. Method definitions are also executable, which allows a program to choose between two versions of a method definition during execution, simply by putting the two definitions in the then and else clause of a selection construct.

Ruby objects are created with **`new`**, which implicitly calls a constructor. The usual constructor in a Ruby class is named `initialize`. A constructor in a subclass can initialize the data members of the parent class that have setters defined. This is done by calling **`super`** with the initial values as actual parameters. **`super`** calls the method in the parent class that has the same name as the method in which the call to **`super`** appears.

Ruby classes can be nested, but the nested class has no special access to the variables or methods of the nesting class.

All variables in Ruby are references to objects, and all are typeless. Recall that the names of all instance variables in Ruby begin with an at sign (`@`).

In a clear departure from the other common programming languages, access control in Ruby is different for data than it is for methods. All instance data has private access by default, and that cannot be changed. Therefore, no subclass in Ruby is a subtype. If external access to an instance variable is required, accessor methods must be defined. For example, consider the following skeletal class definition:

```
class MyClass
# A constructor
  def initialize
    @one = 1
    @two = 2
  end
```

```
# A getter for @one
  def one
    @one
  end
# A setter for @one
  def one=(my_one)
    @one = my_one
  end
end  # of class MyClass
```

The equal sign (=) attached to the name of the setter method means that its variable is assignable. So, all setter methods have equal signs attached to their names. The body of the `one` getter method illustrates the Ruby design of methods returning the value of the last expression evaluated when there is no return statement. In this case, the value of `@one` is returned.

Because getter and setter methods are so frequently needed, Ruby provides shortcuts for creating them. If one wants a class to have getter methods for the two instance variables, `@one` and `@two`, those getters can be specified with the single statement in the class:

```
attr_reader :one, :two
```

`attr_reader` is actually a function call, using `:one` and `:two` as the actual parameters. Preceding a variable with a colon (`:`) causes the variable name to be used, rather than dereferencing it to the object to which it refers. Instead of passing a value or an address, the text of the variable's name is passed. This is exactly how macro parameters are passed.

The function that similarly creates setters is called `attr_writer`. This function has the same parameter profile as `attr_reader`.

The functions for creating getter and setter methods are so named because they provide the protocol for objects of the class, which then are called **attributes**. So, the attributes of a class define the data interface (the data made public through accessor methods) to objects of the class.

Class variables, which are specified by preceding their names with two at signs (@@), are private to the class and its instances. That privacy cannot be changed. Also, unlike global and instance variables, class variables must be

initialized before they are used.

12.4.5.2 Inheritance

Subclasses are defined in Ruby using the less-than symbol (<), rather than the colon of C++. For example,

```
class MySubClass < BaseClass
```

One distinct thing about the method access controls of Ruby is that they can be changed in a subclass, simply by calling the access control functions. This means that two subclasses of a base class can be defined so that objects of one of the subclasses can access a method defined in the base class, but objects of the other subclass cannot. Also, this allows one to change the access of a publicly accessible method in the base class to a privately accessible method in the subclass.

12.4.5.3 Dynamic Binding

Support for dynamic binding in Ruby is the same as it is in Smalltalk. - Variables are not typed; rather, they are all references to objects of any class. So, all variables are polymorphic and all bindings of method calls to methods are dynamic.

12.4.5.4 Evaluation

Because Ruby is an object-oriented programming language in the purest sense, its support for object-oriented programming is obviously adequate. However, access control to class members is weaker than that of C++. Ruby does not support abstract classes or interfaces, although its mixins are closely related to interfaces. Finally, in large part because Ruby is interpreted, its execution efficiency is far worse than that of the compiled languages.

Table 12.1 summarizes how the designers of the languages in this section chose to deal with the design issues described in Section 12.3.

Table 12.1 Designs

DESIGN ISSUE/ LANGUAGE	SMALLTALK	C++	JAVA	C#	RUBY
Exclusivity of objects	All data are objects	Primitive types plus objects	Primitive types plus objects	Primitive types plus objects	All data are objects
Are subclasses subtypes?	They can be and usually are	They can be and usually are if the derivation is public	They can be and usually are	They can be and usually are	No subclasses are subtypes
Single and multiple inheritance	Single only	Both	Single only, but some effects with interfaces	Single only, but some effects with interfaces	Single only, but some effects with modules
Allocation and deallocation of objects	All objects are heap allocated; allocation is explicit and deallocation is implicit	Objects can be static, stack dynamic, or heap dynamic; allocation and deallocation are explicit	All objects are heap dynamic; allocation is explicit and deallocation is implicit	All objects are heap dynamic; allocation is explicit and deallocation is implicit	All objects are heap dynamic; allocation is explicit and deallocation is implicit
Dynamic and static binding	All method bindings are dynamic	Method binding can be either	Method binding can be either	Method binding can be either	All method bindings are dynamic
Nested classes?	No	Yes	Yes	Yes	Yes
Initialization	Constructors must be explicitly called	Constructors are implicitly called	Constructors are implicitly called	Constructors are implicitly called	Constructors are implicitly called

12.5 Implementation of Object-Oriented Constructs

There are at least two parts of language support for object-oriented programming that pose interesting questions for language implementers: storage structures for instance variables and the dynamic bindings of messages to methods. In this section, we provide a brief look at these.

12.5.1 Instance Data Storage

In C++, classes are defined as extensions of C's record structures—structs. This similarity suggests a storage structure for the instance variables of class instances—that of a record. This form of this structure is called a **class instance record (CIR)**. The structure of a CIR is static, so it is built at compile time and used as a template for the creation of the data of class instances. Every class has its own CIR. When a derivation takes place, the CIR for the subclass is a copy of that of the parent class, with entries for the new instance variables added at the end.

Because the structure of the CIR is static, access to all instance variables can be done as it is in records, using constant offsets from the beginning of the CIR instance. This makes these accesses as efficient as those for the fields of records.

12.5.2 Dynamic Binding of Method Calls to Methods

Methods in a class that are statically bound need not be involved in the CIR for the class. However, methods that will be dynamically bound must have entries in this structure. Such entries could simply have a pointer to the code

of the method, which must be set at object creation time. Calls to a method could then be connected to the corresponding code through this pointer in the CIR. The drawback to this technique is that every instance would need to store pointers to all dynamically bound methods that could be called from the instance.

Notice that the list of dynamically bound methods that can be called from an instance of a class is the same for all instances of that class. Therefore, the list of such methods must be stored only once. So the CIR for an instance needs only a single pointer to that list to enable it to find called methods. The storage structure for the list is often called a **virtual method table (vtable)**. Method calls can be represented as offsets from the beginning of the vtable. Polymorphic variables of an ancestor class always reference the CIR of the correct type object, so getting to the correct version of a dynamically bound method is assured. Consider the following Java example, in which all methods are dynamically bound:

```
public class A {
  public int a, b;
  public void draw() { . . . }
  public int area() { . . . }
}
public class B extends A {
  public int c, d;
  public void draw() { . . . }
  public void sift() { . . . }
}
```

The CIRs for the `A` and `B` classes, along with their vtables, are shown in Figure 12.7. Notice that the method pointer for the `area` method in B's vtable points to the code for A's `area` method. The reason is that B does not override A's `area` method, so if a client of B calls `area`, it is the `area` method inherited from A. On the other hand, the pointers for `draw` and `sift` in B's vtable point to B's `draw` and `sift`. The `draw` method is overridden in B and `sift` is defined as an addition in B.

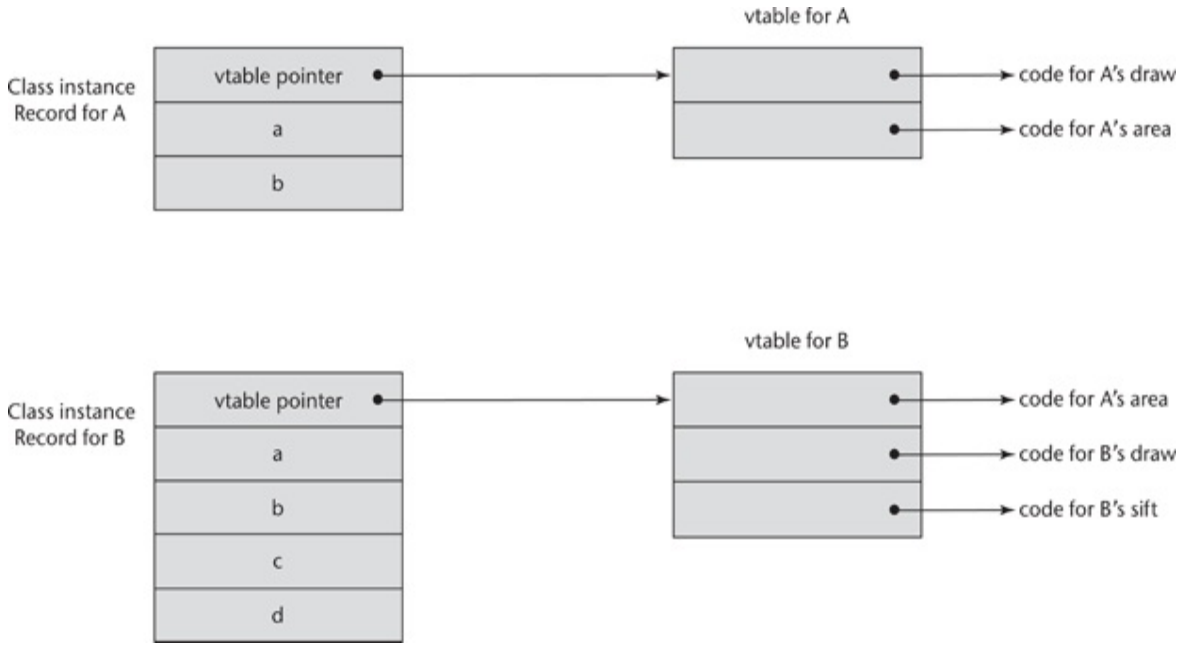

Figure 12.7 An example of the CIRs with single inheritance

Figure 12.7 Full Alternative Text

Multiple inheritance complicates the implementation of dynamic binding. Consider the following three C++ class definitions:

```
class A {
  public:
     int a;
     virtual void fun() { . . . }
     virtual void init() { . . . }
};
 class B {
   public:
     int b;
     virtual void  sum() { . . . }
};
class C : public A, public B {
  public:
    int  c;
    virtual void fun() { . . . }
```

```
    virtual void dud() { . . . }
};
```

The C class inherits the variable a and the init method from the A class. It redefines the fun method, although both its fun and that of the parent class A are potentially visible through a polymorphic variable (of type A). From B, C inherits the variable b and the sum method. C defines its own variable, c, and defines an uninherited method, dud. A CIR for C must include A's data, B's data, and C's data, as well as some means of accessing all visible methods. Under single inheritance, the CIR would include a pointer to a vtable that has the addresses of the code of all visible methods. With multiple inheritance, however, it is not that simple. There must be at least two different views available in the CIR—one for each of the parent classes, one of which includes the view for the subclass, C. This inclusion of the view of the subclass in the parent class's view is just as in the implementation of single inheritance.

There must also be two vtables: one for the A and C view and one for the B view. The first part of the CIR for C in this case can be the C and A view, which begins with a vtable pointer for the methods of C and those inherited from A, and includes the data inherited from A. Following this in C's CIR is the B view part, which begins with a vtable pointer for the virtual methods of B, which is followed by the data inherited from B and the data defined in C. The CIR for C is shown in Figure 12.8.

12.6 Reflection

A discussion of reflection is not a perfect fit into a chapter on object orientation, but it is even a worse fit into any other chapter of this book. So, this is where we put it.

12.6.1 Introduction

In general, the later bindings take place in a programming language, the more flexible the language is. For example, the late binding of data types in scripting languages and functional languages allows their programs to be more generic than those in the static-typed languages. Likewise, the dynamic binding of method calls to methods that is part of the object-oriented languages allows their programs to be easier to maintain and extend. Among other things, reflection provides the possibility of late binding of calls to methods that are outside the inheritance hierarchy of the calling code.

12.6.2 What Is Reflection?

A programming language that supports reflection allows its programs to have run-time access to their types and structure and to be able to dynamically modify their behavior. To allow a program to examine its types and structure, that information must be gathered by the compiler or interpreter and made available to the program. Just as information about the structure of a database is called metadata, the types and structure of a program are called **metadata**. The process of a program examining its metadata is called **introspection**. A program can modify its behavior dynamically in several different ways: it could change its metadata directly, it could use the metadata, or it could intercede in the execution of the program. The first of these is complicated; the second is less complex and is common among languages; the third often is called **intercession**.

Some of the primary uses of reflection are in the construction of software tools. A class browser needs to enumerate the classes of a program. Visual Integrated Development Environments can use type information to assist a developer in building type-correct code. Debuggers must be able to examine private fields and methods of classes. Test systems need to be able to discover all of the methods of a class to be sure that test data drives all of them.

To illustrate a relatively simple and common use of reflection, we pose the following problem. A zoo has a large area devoted to birds. The flight cage for each species includes a plaque that provides general information about the inhabitant's species. Included on the plaque is a small screen onto which a visitor with special interest in the species can enter his or her entrance ticket number. At the exit to the bird exhibit, the visitor can again enter his or her ticket number on a small screen, which causes a computer to print pictures of the birds for which the visitor previously indicated particular interest. The computer system that supports these activities has an object that includes a method that draws a picture of its bird for each of the birds on display. This seems simple enough. When a visitor selects a bird at its flight cage, the system places a reference to an object associated with that bird in a list. At the exit of the exhibit, the system calls the draw method of each object in the visitor's list. The process is complicated by the fact that the zoo supplies only some of the bird objects. Some of them are purchased from third-party vendors and some are donated by zoo benefactors. Because of the multiple sources of the bird objects, they do not have a common base class (other than Object) and do not implement a common interface, so what type references can be saved? One obvious solution is to make each bird object the subclass of a base class. References of the base class type could be stored in the list and dynamic binding could be used to invoke the draw methods. The drawback of this approach is that every bird class would need to be modified to make the new classes subclasses of the common base class. It would be better if the new bird classes could simply be added to a code file without modification. Another possible solution would be to use instance of and casting to determine the concrete types of the references. This would add much code to the system, increasing its complexity and cost of maintenance. A better solution is to use the dynamic binding that is possible with reflection.

12.6.3 Reflection in Java

Java provides limited support for reflection. The primary class of the metadata is defined in the namespace, `java.lang.Class`.[14] This class has the unfortunately confusing name, `Class`. The Java run-time system instantiates an instance of `Class` for each object in the program. The `Class` class provides a collection of methods to examine the type information and members of the program objects. `Class` is the access point for all of the reflection API.

14. It is so named because its instantiations are themselves classes.

If the program has a reference to an object (not a primitive), the `Class` object of that object can be obtained by calling its `getClass` method. All classes inherit `getClass` from `Object`, from which all objects descend. Consider the following examples:

```
float[] totals = new float[100];
Class fltlist = totals.getClass();
Class stg = "hello".getClass();
```

The value of the variable `fltlist` will be the `Class` object of the `totals` array object. The value of `stg` will be the `Class` object of `String` (because `"hello"` is an instance of `String`).

If there is no object of a class, its `Class` object can be obtained through the class' name by attaching `.class` to the name. For example, we could have the following:

```
Class stg = String.class;
```

If the class has no name, its `Class` object can still be obtained by attaching `.class` to the class definition. For example, consider the following:

```
Class intmat = int[][].class;
```

The `.class` modifier can also be attached to primitive types. Although `float.getClass()` is illegal, `float.class` is not.

There are four methods to get the `Class` of a method. The `getMethod` method searches a class to find a specific public method defined in the class or inherited by the class. The `getMethods` method returns an array of all of the public methods defined in a class or inherited by the class. The `getDeclaredMethod` method searches for a specific method declared in a class, including private methods. The `getDeclaredMethods` method returns all of the methods defined in a class.

If the `Class` object of an object is known and a particular method defined by the class of the object is found, that method can be called through the `Method` object of the method with the `invoke` method. For example, if the `Method` object named `method` is found with `getMethod`, it can be called with the following:

```
method.invoke(...);
```

We can now develop a solution in Java for the problem posed in Section 12.6.2. The heart of this application is a class that defines a method that is passed an `Object` reference. The method determines the class of the passed reference, finds a `draw` method of that class, and calls that method. The solution class is tested with a second class, `ReflectTest`, which creates an array of three `Object` references to classes that represent three different birds. Each of these defines a `draw` method that, when called, displays a message indicating that it was called. Then the test calls the class method, passing the elements of the array of references.

The caller method can raise three different exceptions, each of which is handled in the method.

```
// A project to illustrate dynamic method calling
// using reflection in Java
package reflect;
import java.lang.reflect.*;
// A class to test the Reflect class
//  Creates three objects that represent different birds
//  and calls a method that dynamically calls the draw
//  methods of the three bird classes
public class ReflectTest {
   public static void main(String[] args) {
        Object[] birdList = new Object[3];
        birdList[0] = new Bird1();
```

```
        birdList[1] = new Bird2();
        birdList[2] = new Bird3();
        Reflect.callDraw(birdList[2]);
        Reflect.callDraw(birdList[0]);
        Reflect.callDraw(birdList[1]);
       }
}
// A class to define the method that dynamically calls the
//  methods of a passed class object
class Reflect {
    public static void callDraw(Object birdObj) {
        Class cls = birdObj.getClass();
        try {
            // Find the draw method of the given class
            Method method = cls.getMethod("draw");
            // Dynamically call the method
            method.invoke(birdObj);
        }
        // In case the given class does not support draw
        catch (NoSuchMethodException e) {
            throw new IllegalArgumentException (
                cls.getName() + "does not support draw");
        }
        // In case the callDraw cannot call draw
        catch (IllegalAccessException e) {
            throw new IllegalArgumentException (
                "Insufficient access permissions to call" +
                "draw in class " + cls.getName());
        }
        // In case draw throws an exception
        catch (InvocationTargetException e) {
            throw new RuntimeException(e);
        }
      }
}
class Bird1 {
  public void draw() {
      System.out.println("This is draw from Bird1");
  }
}
class Bird2 {
    public void draw() {
        System.out.println("This is draw from Bird2");
    }
}
class Bird3 {
    public void draw() {
        System.out.println("This is draw from Bird3");
```

```
    }
]
```

The output of this program is as follows:

```
This is the draw from Bird3
This is the draw from Bird1
This is the draw from Bird2
```

12.6.4 Reflection in C#

Support for reflection in C# is similar to that of Java, with a few important differences. In C#, as in all .NET languages, the compiler places the intermediate code, written in Common Intermediate Language (CIL), in an assembly, which could include several files. An assembly also contains an assembly version number and the metadata for all classes defined in the assembly, as well as for all external classes it uses.

Instead of the `java.lang.Class` namespace, `System.Type` is used in .NET; instead of `java.lang.reflect`, `System.Reflection` is used. Rather than the `getClass` method, `getType` is used to get the class of an instance. Also, the .NET languages use the `typeof` operator in place of the `.class` field used in Java. Following is a C# version of the Java project shown above:

```
using System;
using System.Reflection;
namespace TestReflect
{
// A project to illustrate dynamic method calling
// using reflection in C#
// A class to test the Reflect class
//  Creates three objects that represent different birds
//  and calls a method that dynamically calls the draw
//  methods of the three bird classes
public class ReflectTest {
   public static void Main(String[] args) {
        Object[] birdList = new Object[3];
        birdList[0] = new Bird1();
        birdList[1] = new Bird2();
        birdList[2] = new Bird3();
        Reflect.callDraw(birdList[2]);
```

```
        Reflect.callDraw(birdList[0]);
        Reflect.callDraw(birdList[1]);
        }
}
// A class to define the method that dynamically calls the
//  methods of a passed class object
class Reflect {
    public static void callDraw(Object birdObj) {
        Type typ = birdObj.GetType();
            // Find the draw method of the given class
            MethodInfo method = typ.GetMethod("draw");
            // Dynamically call the method
            method.Invoke(birdObj, null);
    }
}
class Bird1 {
    public void draw() {
        Console.WriteLine("This is draw from Bird1");
    }
}
class Bird2 {
    public void  draw() {
        Console.WriteLine("This is draw from Bird2");
    }
}
class Bird3 {
    public void draw() {
        Console.WriteLine("This is draw from Bird3");
    }
}
}
```

Our simple example of dynamic method binding shows just one of the many uses of reflection.

In addition to the methods and fields of a class, the following program elements can be accessed with reflection in both Java and C#: class modifiers, such as public, static, and final, constructors, method parameter types, and implemented interfaces. Also, a description of the inheritance path of a class can be introspected. In C#, but not Java, the names of the formal parameters of methods can be discovered.

One significant difference between Java's reflection and that of C# is the `System.Reflection.Emit` namespace, which is part of .NET. This

namespace provides the ability to create CIL code and an assembly to house that code. Java provides no such capability, although it can be done with tools from other suppliers.

Although reflection adds a variety of capabilities to the static-typed languages Java and C#, the user of reflection must be aware of its downsides:

- Performance nearly always suffers with the use of reflection. Resolving types, methods, and fields at run time are not part of the cost of running nonreflective code. Also, when types are dynamically resolved, some optimizations cannot be done on the code.

- Reflection exposes private fields and methods, which violate the rules of abstraction and information hiding, and also may result in unexpected side effects and adversely affect portability.

- Although the advantage of early type checking is widely accepted, the late binding that is possible with reflection obviously negates that advantage.

- Some reflective operations may not work when the code is run under a security manager, also making it non-portable. One such security environment is that of running applets. In most cases, if a problem can be solved without reflection, reflection should not be used.

Reflection is an integral part of most dynamically typed languages. In LISP, reflection is routinely used and the dynamic construction and execution of code is not uncommon. In other interpreted languages, such as JavaScript, Perl, and Python, the symbol table is kept during interpretation, providing all useful type information.

In Python, for example, the `type` method returns the type of a given value. For example, `type([7, 14, 21])` is `list`. The `isinstance` method returns a Boolean value if its first parameter has the type named in its second parameter. For example, `isinstance(17, int)` returns `True`. The `callable` function is used to determine whether an expression returns a function object. The `dir` function returns the list of attributes, both data and methods, of its parameter object.

SUMMARY

Object-oriented programming is based on three fundamental concepts: abstract data types, inheritance, and dynamic bindinwg. Object-oriented programming languages support the paradigm with classes, methods, objects, and message passing.

The discussion of object-oriented programming languages in this chapter revolves around seven design issues: exclusivity of objects, subclasses and subtypes, type checking and polymorphism, single and multiple inheritance, dynamic binding, explicit or implicit deallocation of objects, and nested classes.

Smalltalk is a pure object-oriented language—everything is an object and all computation is accomplished through message passing. All type checking and binding of messages to methods is dynamic, and all inheritance is single. Smalltalk has no explicit deallocation operation.

C++ provides support for data abstraction, inheritance, and optional dynamic binding of messages to methods, along with all of the conventional features of C. This means that it has two distinct type systems. C++ provides multiple inheritance and explicit object deallocation. It includes a variety of access controls for the entities in classes, some of which prevent subclasses from being subtypes. Both constructor and destructor methods can be included in classes; both are usually implicitly called.

While Smalltalk’s dynamic type binding provides somewhat more programming flexibility than the hybrid language C++, it is far less efficient.

Unlike C++, Java is not a hybrid language; it is meant to support only object-oriented programming. Java has both primitive scalar types and classes. All objects are allocated from the heap and are accessed through reference variables. There is no explicit object deallocation operation—garbage collection is used. The only subprograms are methods, and they can be called only through objects or classes. Only single inheritance is directly supported,

although a kind of multiple inheritance is possible using interfaces. All binding of messages to methods is dynamic, except in the case of methods that cannot be overridden. In addition to classes, Java includes packages as a second encapsulation construct.

C#, which is based on C++ and Java, supports object-oriented programming. Objects can be instantiated from either classes or structs. The struct objects are stack dynamic and do not support inheritance. Methods in a derived class can call the hidden methods of the parent class by including **`base`** on the method name. Methods that can be overridden must be marked **`virtual`**, and the overriding methods must be marked with **`override`**. All classes (and all primitives) are derived from `Object`.

Ruby is an object-oriented scripting language in which all data are objects. As with Smalltalk, all objects are heap allocated and all variables are typeless references to objects. All constructors are named `initialize`. All instance data are private, but getter and setter methods can be easily included. The collection of all instance variables for which access methods have been provided forms the public interface to the class. Such instance data are called attributes. Ruby classes are dynamic in the sense that they are executable and can be changed at any time. Ruby supports only single inheritance.

The instance variables of a class are stored in a CIR, the structure of which is static. Subclasses have their own CIRs, as well as the CIR of their parent class. Dynamic binding is supported with a virtual method table, which stores pointers to specific methods. Multiple inheritance greatly complicates the implementation of CIRs and virtual method tables.

Reflection is a process by which a program can access its classes and types and possibly dynamically change them to affect program behavior. One of the primary uses of reflection is in the construction of software tools, such as visual program construction tools, debuggers, and test systems. The class and type information, called metadata, is collected by the compiler or interpreter for the language. In Java, the class information, such as the methods of the class, are available in the `Class` object of a class. Support for reflection in C#, which is similar to that of Java, is available in the `System.Reflection` namespace.

REVIEW QUESTIONS

1. Describe the three characteristic features of object-oriented languages.
2. What is the difference between a class variable and an instance variable?
3. What is multiple inheritance?
4. What is a polymorphic variable?
5. What is an overriding method?
6. Describe a situation where dynamic binding is a great advantage over static binding.
7. What is a virtual method?
8. What is an abstract method? What is an abstract class?
9. Describe briefly the seven design issues used in this chapter for object-oriented languages.
10. What is a nesting class?
11. What is the message protocol of an object?
12. From where are Smalltalk objects allocated?
13. Explain how Smalltalk messages are bound to methods. When does this take place?
14. What type checking is done in Smalltalk? When does it take place?
15. What kind of inheritance, single or multiple, does Smalltalk support?
16. What are the two most important effects that Smalltalk has had on computing?

17. In essence, all Smalltalk variables are of a single type. What is that type?

18. From where can C++ objects be allocated?

19. How are C++ heap-allocated objects deallocated?

20. Are all C++ subclasses subtypes? If so, explain. If not, why not?

21. Under what circumstances is a C++ method call statically bound to a method?

22. What drawback is there to allowing designers to specify which methods can be statically bound?

23. What are the differences between private and public derivations in C++?

24. What is a `friend` function in C++?

25. What is a pure virtual function in C++?

26. How are parameters sent to a superclass's constructor in C++?

27. What is the single most important practical difference between Smalltalk and C++?

28. How is the type system of Java different from that of C++?

29. From where can Java objects be allocated?

30. What is boxing?

31. How are Java objects deallocated?

32. Are all Java subclasses subtypes?

33. How are superclass constructors called in Java?

34. Under what circumstances is a Java method call statically bound to a method?

35. In what way do overriding methods in C# syntactically differ from their counterparts in C++?

36. How can the parent version of an inherited method that is overridden in a subclass be called in that subclass in C#?

37. How does Ruby implement primitive types, such as those for integer and floating-point data?

38. How are getter methods defined in a Ruby class?

39. What access controls does Ruby support for instance variables?

40. What access controls does Ruby support for methods?

41. Are all Ruby subclasses subtypes?

42. Does Ruby support multiple inheritance?

43. What does reflection allow a program to do?

44. In the context of reflection, what is metadata?

45. What is introspection?

46. What is intercession?

47. What class in Java stores information about classes in a program?

48. For what is the Java name extension `.class` used?

49. What does the Java `getMethods` method do?

50. For what is the C# namespace `System.Reflection.Emit` used?

PROBLEM SET

1. What important part of support for object-oriented programming is missing in SIMULA 67?

2. Explain the principle of substitution.

3. Explain the ways subclasses can be created that are not subtypes.

4. Compare the dynamic binding of C++ and Java.

5. Compare the class entity access controls of C++ and Java.

6. Compare the multiple inheritance of C++ with that provided by interfaces in Java.

7. What is one programming situation where multiple inheritance has a significant advantage over interfaces?

8. Explain the two problems with abstract data types that are ameliorated by inheritance.

9. Describe the categories of changes that a subclass can make to its parent class.

10. Explain one disadvantage of inheritance.

11. Explain the advantages and disadvantages of having all values in a language be objects.

12. What exactly does it mean for a subclass to have an is-a relationship with its parent class?

13. Describe the issue of how closely the parameters of an overriding method must match those of the method it overrides.

14. Explain type checking in Smalltalk.

15. The designers of Java obviously thought it was not worth the additional efficiency of allowing any method to be statically bound, as is the case with C++. What are the arguments for and against the Java design?

16. What is the primary reason why all Java objects have a common ancestor?

17. What is the purpose of the **`finalize`** clause in Java?

18. What would be gained if Java allowed stack-dynamic objects as well as heap-dynamic objects? What would be the disadvantage of having both?

19. What are the differences between a C++ abstract class and a Java interface?

20. Explain why allowing a class to implement multiple interfaces in Java and C# does not create the same problems that multiple inheritance in C++ creates.

21. Study and explain the issue of why C# does not include Java's nonstatic nested classes.

22. Can you define a reference variable for an abstract class? What use would such a variable have?

23. Compare the access controls for instance variables in Java and Ruby.

24. Compare the type error detection for instance variables in Java and Ruby.

25. Explain the downsides of reflection.

PROGRAMMING EXERCISES

1. Rewrite the `single_linked_list`, `stack_2`, and `queue_2` classes in Section 12.5.2 in Java and compare the result with the C++ version in terms of readability and ease of programming.

2. Repeat Programming Exercise 1 using Ruby.

3. Design and implement a C++ program that defines a base class A, which has a subclass B, which itself has a subclass C. The A class must implement a method, which is overridden in both B and C. You must also write a test class that instantiates A, B, and C and includes three calls to the method. One of the calls must be statically bound to A's method. One call must be dynamically bound to B's method, and one must be dynamically bound to C's method. All of the method calls must be through a pointer to class A.

4. Write a program in C++ that calls both a dynamically bound method and a statically bound method a large number of times, timing the calls to both of the two. Compare the timing results and compute the difference of the time required by the two. Explain the results.

5. Repeat Programming Exercise 1 using Java, forcing static binding with **`final`**.

13 Concurrency

This chapter begins with introductions to the various kinds of concurrency at the subprogram, or unit level, and at the statement level. Included is a brief description of the most common kinds of multiprocessor computer architectures. Next, a lengthy discussion on unit-level concurrency is presented. This begins with a description of the fundamental concepts that must be understood before discussing the problems and challenges of language support for unit-level concurrency, specifically competition and cooperation synchronization. Next, the design issues for providing language support for concurrency are described. Following this is a detailed discussion of three major approaches to language support for concurrency: semaphores, monitors, and message passing. A pseudocode example program is used to - demonstrate how semaphores can be used. Ada and Java are used to illustrate monitors; for message passing, Ada is used. The Ada features that support concurrency are described in some detail. Although tasks are the focus,

protected objects (which are effectively monitors) are also discussed. Support for unit-level concurrency using threads in Java and C# is then discussed, including approaches to synchronization. This is followed by brief overviews of support for concurrency in several functional programming languages. The last section of the chapter is a brief discussion of statement-level concurrency, including an introduction to part of the language support provided for it in High-Performance Fortran.

13.1 Introduction

Concurrency in software execution can occur at four different levels: instruction level (executing two or more machine instructions simultaneously), statement level (executing two or more high-level language statements simultaneously), unit level (executing two or more subprogram units simultaneously), and program level (executing two or more programs simultaneously). Because no language design issues are involved with them, instruction-level and program-level concurrency are not discussed in this chapter. Concurrency at both the subprogram and the statement levels is discussed, with most of the focus on the subprogram level.

At first glance, concurrency may appear to be a simple concept, but it presents significant challenges to the programmer, the programming language designer, and the operating system designer (because much of the support for concurrency is provided by the operating system).

Concurrent control mechanisms increase programming flexibility. They were originally invented to be used for particular problems faced in operating systems, but they are required for a variety of other programming applications. One of the most commonly used programs is Web browsers, whose design is based heavily on concurrency. Browsers must perform many different functions at the same time, among them sending and receiving data from Web servers, rendering text and images on the screen, and reacting to user actions with the mouse and the keyboard. Most contemporary browsers use the extra core processors that are part of many contemporary personal computers to perform some of their processing, for example the interpretation of client-side scripting code. Another example is the software systems that are designed to simulate actual physical systems that consist of multiple concurrent subsystems. For all of these kinds of applications, the programming language (or a library or at least the operating system) must support unit-level concurrency.

Statement-level concurrency is quite different from concurrency at the unit level. From a language designer’s point of view, statement-level concurrency

is largely a matter of specifying how data should be distributed over multiple memories and which statements can be executed concurrently.

The goal of developing concurrent software is to produce scalable and portable concurrent algorithms. A concurrent algorithm is **scalable** if the speed of its execution increases when more processors are available. This is important because the number of processors sometimes increases with the new generations of machines. The algorithms must be portable because the lifetime of hardware is relatively short. Therefore, software systems should not depend on a particular architecture—that is, they should run efficiently on machines with different architectures.

The intention of this chapter is to discuss the aspects of concurrency that are most relevant to language design issues, rather than to present a definitive study of all of the issues of concurrency, including the development of concurrent programs. That would clearly be inappropriate for a book on programming languages.

13.1.1 Multiprocessor Architectures

A large number of different computer architectures have more than one processor and can support some form of concurrent execution. Before beginning to discuss concurrent execution of programs and statements, we briefly describe some of these architectures.

The first computers that had multiple processors had one general-purpose processor and one or more other processors, often called peripheral processors, that were used only for input and output operations. This architecture allowed those computers, which appeared in the late 1950s, to execute one program while concurrently performing input or output for that program or other programs.

By the early 1960s, there were machines that had multiple complete processors. These processors were used by the job scheduler of the operating

system, which distributed separate jobs from a batch-job queue to the separate processors. Systems with this structure supported program-level concurrency.

In the mid-1960s, some machines appeared that had several identical partial processors. These were fed instructions from a single instruction stream. For example, some machines had two or more floating-point multipliers, while others had two or more complete floating-point arithmetic units. The compilers for these machines were required to determine which instructions could be executed concurrently and to schedule these instructions accordingly. Systems with this structure supported instruction-level concurrency.

In 1966, Michael J. Flynn suggested a categorization of computer architectures defined by whether the instruction and data streams were single or multiple. The names of these were widely used from the 1970s to the early 2000s. The two categories that used multiple data streams are defined as follows: Computers that have multiple processors that execute the same instruction simultaneously, each on different data, are called Single Instruction, Multiple Data (SIMD) architecture computers. In an SIMD computer, each processor has its own local memory. One processor controls the operation of the other processors. Because all of the processors, except the controller, execute the same instruction at the same time, no synchronization is required in the software. Perhaps the most widely used SIMD machines are a category of machines called **vector processors**. They have groups of registers that store the operands of a vector operation in which the same instruction is executed on the whole group of operands simultaneously. Originally, the kinds of programs that could most benefit from this architecture were in scientific computation, an area of computing that is often the target of multiprocessor machines. However, SIMD processors are now used for a variety of application areas, among them graphics and video processing. Until recently, most supercomputers were vector processors.

Computers that have multiple processors that operate independently but whose operations can be synchronized are called Multiple Instruction, Multiple Data (MIMD) computers. Each processor in an MIMD computer

executes its own instruction stream. MIMD computers can appear in two distinct configurations: distributed and shared memory systems. The distributed MIMD machines, in which each processor has its own memory, can be either built in a single chassis or distributed, perhaps over a large area. The shared-memory MIMD machines obviously must provide some means of synchronization to prevent memory access clashes. Even distributed MIMD machines require synchronization to operate together on single programs. MIMD computers, which are more general than SIMD computers, support unit-level concurrency. The primary focus of this chapter is on language design for shared memory MIMD computers, which are often called **multiprocessors**.

With the advent of powerful but low-cost single-chip computers, it became possible to have large numbers of these microprocessors connected into physically small networks within a single chassis. These kinds of computers, which often use off-the-shelf microprocessors, are available from a number of different manufacturers.

One important reason why software has not evolved faster to make use of concurrent machines is that the power of processors has continually increased. One of the strongest motivations to use concurrent machines is to increase the speed of computation. However, two hardware factors have combined to provide faster computation, without requiring any change in the architecture of software systems. First, processor clock rates have become faster with each new generation of processors (the generations have appeared roughly every 18 months). Second, several different kinds of concurrency have been built into the processor architectures. Among these are the pipelining of instructions and data from the memory to the processor (instructions are fetched and decoded for future execution while the current instruction is being executed), the use of separate lines for instructions and data, prefetching of instructions and data, and parallelism in the execution of arithmetic operations. All of these are collectively called **hidden concurrency**. The result of the increases in execution speed is that there have been great productivity gains without requiring software developers to produce concurrent software systems.

However, the situation has changed. The end of the sequence of significant

increases in the speed of individual processors is now near. Significant increases in computing power now result from increases in the number of processors, for example large server systems like those run by Google and Amazon and scientific research applications. Many other large computing tasks are now run on machines with large numbers of relatively small processors.

Another recent advance in computing hardware was the development of multiple processors on a single chip, such as with the Intel Core Duo and Core Quad chips, which is putting more pressure on software developers to make more use of the available multiple processor machines. If they do not, the concurrent hardware will be wasted and significant productivity gains will not be realized.

13.1.2 Categories of Concurrency

There are two distinct categories of concurrent unit control. The most natural category of concurrency is that in which, assuming that more than one processor is available, several program units from the same program literally execute simultaneously. This is **physical concurrency**. A slight relaxation of this concept of concurrency allows the programmer and the application software to assume that there are multiple processors providing actual concurrency, when in fact the actual execution of programs is taking place in interleaved fashion on a single processor. This is **logical concurrency**. From the programmer's and language designer's points of view, logical concurrency is the same as physical concurrency. It is the language implementor's task, using the capabilities of the underlying operating system, to map the logical concurrency to the host hardware. Both logical and physical concurrencies allow the concept of concurrency to be used as a program design methodology. For the remainder of this chapter, the discussion will apply to both physical and logical concurrencies.

One useful technique for visualizing the flow of execution through a program is to imagine a thread laid on the statements of the source text of the program. Every statement reached on a particular execution is covered by the thread representing that execution. Visually following the thread through the source

program traces the execution flow through the executable version of the program. Of course, in all but the simplest of programs, the thread follows a highly complex path that would be impossible to follow visually. Formally, a **thread of control** in a program is the sequence of program points reached as control flows through the program.

Programs that have coroutines (see Chapter 9) but no concurrent subprograms, though they are sometimes called **quasi-concurrent**, have a single thread of control. Programs executed with physical concurrency can have multiple threads of control. Each processor can execute one of the threads. Although logically concurrent program execution may actually have only a single thread of control, such programs can be designed and analyzed only by imagining them as having multiple threads of control. A program designed to have more than one thread of control is said to be **multithreaded**. When a multithreaded program executes on a single-processor machine, its threads are mapped onto a single thread. It becomes, in this scenario, a virtually multithreaded program.

Statement-level concurrency is a relatively simple concept. In a common use of statement-level concurrency, loops that include statements that operate on array elements are unwound so that the processing can be distributed over multiple processors. For example, a loop that executes 500 repetitions and includes a statement that operates on one of 500 array elements may be unwound so that each of 10 different processors can simultaneously process 50 of the array elements.

13.1.3 Motivations for the Use of Concurrency

There are at least four different reasons to design concurrent software systems. The first reason is the speed of execution of programs on machines with multiple processors. These machines provide an effective way of increasing the execution speed of programs, provided that the programs are designed to make use of the concurrent hardware. There are now a large number of installed multiple-processor computers, including many of the

personal computers sold in the last few years. It is wasteful not to use this hardware capability.

The second reason is that even when a machine has just one processor, a program written to use concurrent execution can be faster than the same program written for sequential (nonconcurrent) execution. The requirement for this to happen is that the program is not compute bound (the sequential version does not fully utilize the processor).

The third reason is that concurrency provides a different method of conceptualizing program solutions to problems. Many problem domains lend themselves naturally to concurrency in much the same way that recursion is a natural way to design solutions to some problems. Also, many programs are written to simulate physical entities and activities. In many cases, the system being simulated includes more than one entity, and the entities do whatever they do simultaneously—for example, aircraft flying in a controlled airspace, relay stations in a communications network, and the various machines in a factory. Software that uses concurrency must be used to simulate such systems accurately.

The fourth reason for using concurrency is to program applications that are distributed over several machines, either locally or through the Internet. Many machines, for example cars, have more than one built-in computer, each of which is dedicated to some specific task. In many cases, these collections of computers must synchronize their program executions. Internet games are another example of software that is distributed over multiple processors.

Concurrency is now used in numerous everyday computing tasks. Web servers process document requests concurrently. Web browsers now use secondary core processors to run graphic processing and to interpret programming code embedded in documents. In every operating system there are many concurrent processes being executed at all times, managing resources, getting input from keyboards, displaying output from programs, and reading and writing external memory devices. In short, concurrency has become a ubiquitous part of computing.

13.2 Introduction to Subprogram-Level Concurrency

Before language support for concurrency can be considered, one must understand the underlying concepts of concurrency and the requirements for it to be useful. These topics are covered in this section.

13.2.1 Fundamental Concepts

A **task** is a unit of a program, similar to a subprogram, that can be in concurrent execution with other units of the same program. Each task in a program can support one thread of control. Tasks are sometimes called **processes**. In some languages, for example Java and C#, certain methods serve as tasks. Such methods are executed in objects called **threads**.

Three characteristics of tasks distinguish them from subprograms. First, a task may be implicitly started, whereas a subprogram must be explicitly called. Second, when a program unit invokes a task, in some cases it need not wait for the task to complete its execution before continuing its own. Third, when the execution of a task is completed, control may or may not return to the unit that started that execution.

Tasks fall into two general categories: heavyweight and lightweight. Simply stated, a **heavyweight task** executes in its own address space. **Lightweight tasks** all run in the same address space. It is easier to implement lightweight tasks than heavyweight tasks. Furthermore, lightweight tasks can be more efficient than heavyweight tasks, because less effort is required to manage their execution.

A task can communicate with other tasks through shared nonlocal variables, through message passing, or through parameters. If a task does not communicate with or affect the execution of any other task in the program in any way, it is said to be **disjoint**. Because tasks often work together to create

simulations or solve problems and therefore are not disjoint, they must use some form of communication to either synchronize their executions or share data or both.

Synchronization is a mechanism that controls the order in which tasks execute. Two kinds of synchronization are required when tasks share data: cooperation and competition. **Cooperation synchronization** is required between task `A` and task `B` when task `A` must wait for task `B` to complete some specific activity before task `A` can begin or continue its execution. **Competition synchronization** is required between two tasks when both require the use of some resource that cannot be simultaneously used. Specifically, if task `A` needs to access shared data location `x` while task `B` is accessing `x`, task `A` must wait for task `B` to complete its processing of `x`. So, for cooperation synchronization, tasks may need to wait for the completion of specific processing on which their correct operation depends, whereas for competition synchronization, tasks may need to wait for the completion of any other processing by any task currently occurring on specific shared data.

A simple form of cooperation synchronization can be illustrated by a common problem called the **producer-consumer problem**. This problem originated in the development of operating systems, in which one program unit produces some data value or resource and another uses it. Produced data are usually placed in a storage buffer by the producing unit and removed from that buffer by the consuming unit. The sequence of stores to and removals from the buffer must be synchronized. The consumer unit must not be allowed to take data from the buffer if the buffer is empty. Likewise, the producer unit cannot be allowed to place new data in the buffer if the buffer is full. This is a problem of cooperation synchronization because the users of the shared data structure must cooperate if the buffer is to be used correctly.

Competition synchronization prevents two tasks from accessing a shared data structure at exactly the same time—a situation that could destroy the integrity of that shared data. To provide competition synchronization, mutually exclusive access to the shared data must be guaranteed.

To clarify the competition problem, consider the following scenario: Suppose task `A` has the statement `TOTAL += 1`, where `TOTAL` is a shared integer variable. Furthermore, suppose task `B` has the statement `TOTAL *= 2`. Task `A`

and task B could try to change TOTAL at the same time.

At the machine language level, each task may accomplish its operation on TOTAL with the following three-step process:

1. Fetch the value of TOTAL.
2. Perform the arithmetic operation.
3. Put the new value back in TOTAL.

Without competition synchronization, given the previously described operations performed by tasks A and B on TOTAL, four different values could result, depending on the order of the steps of the operations. Assume TOTAL has the value 3 before either A or B attempts to modify it. If task A completes its operation before task B begins, the value will be 8, which is assumed here to be correct. But if both A and B fetch the value of TOTAL before either task puts its new value back, the result will be incorrect. If A puts its value back first, the value of TOTAL will be 6. This case is shown in Figure 13.1. If B puts its value back first, the value of TOTAL will be 4. Finally, if B completes its operation before task A begins, the value will be 7. A situation that leads to these problems is sometimes called a **race condition**, because two or more tasks are racing to use the shared resource and the behavior of the program depends on which task arrives first (and wins the race). The importance of competition synchronization should now be clear.

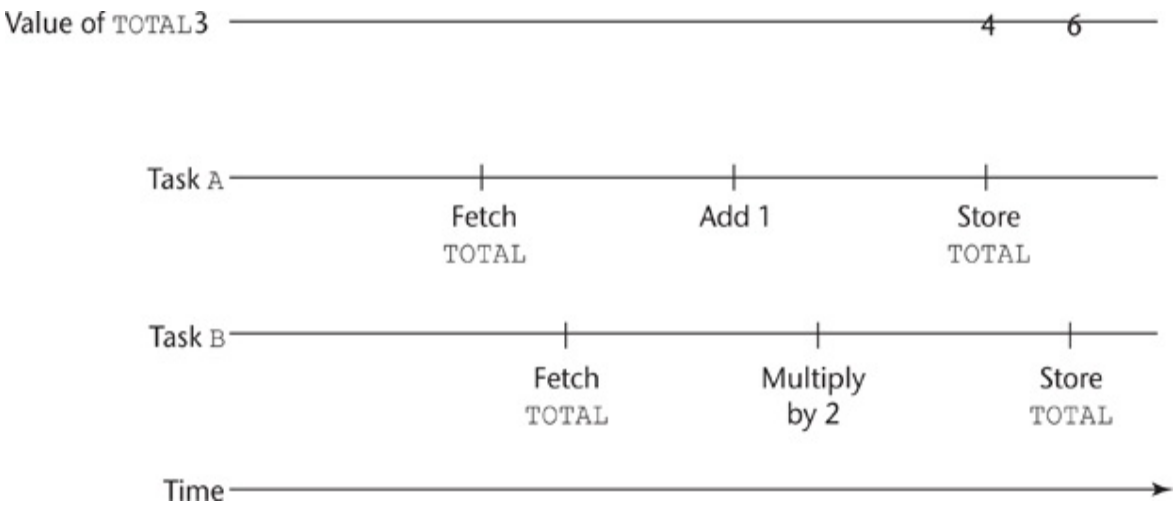

Figure 13.1 The need for - competition synchronization

Figure 13.1 Full Alternative Text

One general method for providing mutually exclusive access (to support competition synchronization) to a shared resource is to consider the resource to be something that a task can possess and allow only a single task to possess it at a time. To gain possession of a shared resource, a task must request it. Possession will be granted only when no other task has possession. While a task possesses a resource, all other tasks are prevented from having access to that resource. When a task is finished with a shared resource that it possesses, it must relinquish that resource so it can be made available to other tasks.

Three methods of providing for mutually exclusive access to a shared resource are semaphores, which are discussed in Section 13.3; monitors, which are discussed in Section 13.4; and message passing, which is discussed in Section 13.5.

Mechanisms for synchronization must be able to delay task execution. Synchronization imposes an order of execution on tasks that is enforced with these delays. To understand what happens to tasks through their lifetimes, we must consider how task execution is controlled. Regardless of whether a machine has a single processor or more than one, there is always the possibility of there being more tasks than there are processors. A run-time system program called a **scheduler** manages the sharing of processors among the tasks. If there were never any interruptions and tasks all had the same priority, the scheduler could simply give each task a time slice, such as 0.1 second, and when a task's turn came, the scheduler could let it execute on a processor for that amount of time. Of course, there are several events that complicate this, for example, task delays for synchronization and for input or output operations. Because input and output operations are very slow relative to the processor's speed, a task is not allowed to keep a processor while it waits for completion of such an operation.

Tasks can be in several different states:

1. New: A task is in the new state when it has been created but has not yet begun its execution.

2. Ready: A ready task is ready to run but is not currently running. Either it has not been given processor time by the scheduler, or it had run previously but was blocked in one of the ways described in Paragraph 4 of this subsection. Tasks that are ready to run are stored in a queue that is often called the **task-ready queue**.

3. Running: A running task is one that is currently executing; that is, it has a processor and its code is being executed.

4. Blocked: A task that is blocked has been running, but that execution was interrupted by one of several different events, the most common of which is an input or output operation. In addition to input and output, some languages provide operations for the user program to specify that a task be blocked.

5. Dead: A dead task is no longer active in any sense. A task dies when its execution is completed or it is explicitly killed by the program.

A flow diagram of the states of a task is shown in Figure 13.2.

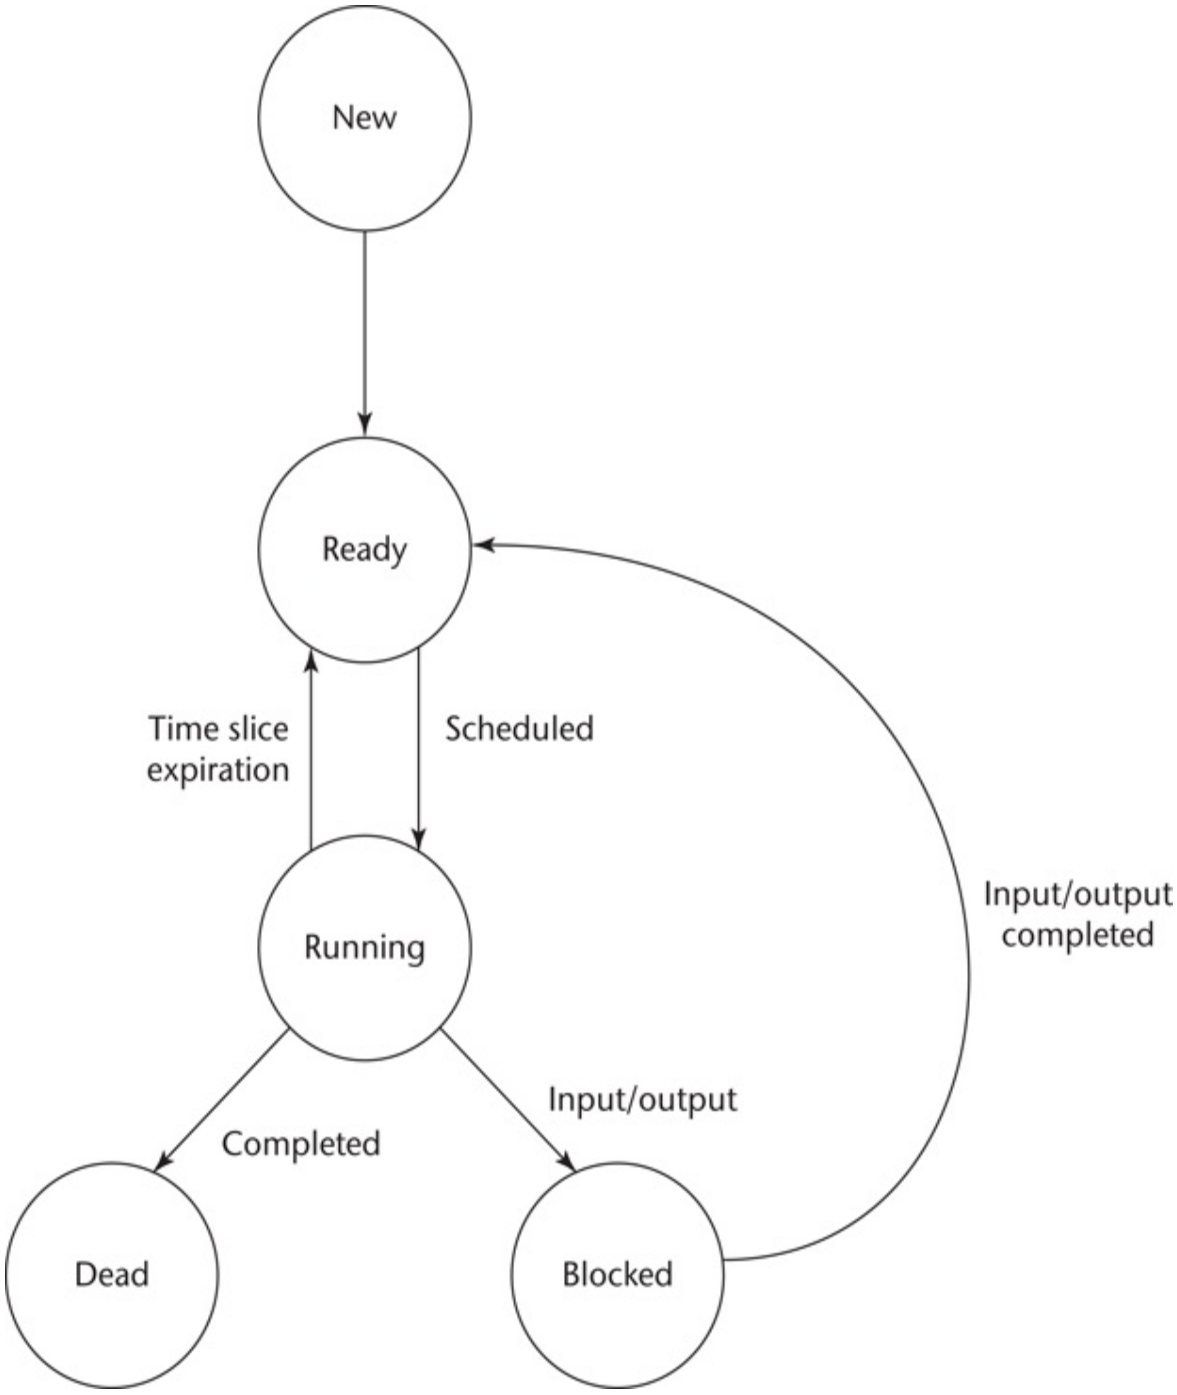

Figure 13.2 Flow diagram of task states

Figure 13.2 Full Alternative Text

One important issue in task execution is the following: How is a ready task chosen to move to the running state when the task currently running has become blocked or whose time slice has expired? Several different algorithms have been used for making this choice, some based on specifiable priority levels. The algorithm that does the choosing is implemented in the scheduler.

Associated with the concurrent execution of tasks and the use of shared resources is the concept of liveness. In the environment of sequential programs, a program has the **liveness** characteristic if it continues to execute, eventually leading to completion. In more general terms, liveness means that if some event—say, program completion—is supposed to occur, it will occur, eventually. That is, progress is continually made. In a concurrent environment and with shared resources, the liveness of a task can cease to exist, meaning that the program cannot continue and thus will never terminate.

For example, suppose task A and task B both need the shared resources X and Y to complete their work. Furthermore, suppose that task A gains possession of X and task B gains possession of Y. After some execution, task A needs resource Y to continue, so it requests Y but must wait until B releases it. Likewise, task B requests X but must wait until A releases it. Neither relinquishes the resource it possesses, and as a result, both lose their liveness, guaranteeing that execution of the program will never complete normally. This particular kind of loss of liveness is called **deadlock**. Deadlock is a serious threat to the reliability of a program, and therefore its avoidance demands serious consideration in both language and program design.

We are now ready to discuss some of the linguistic mechanisms for providing concurrent unit control.

13.2.2 Language Design for Concurrency

In some cases, concurrency is implemented through libraries. Among these is OpenMP, an applications programming interface to support shared memory multiprocessor programming in C, C++, and Fortran on a variety of platforms. Our interest in this book, of course, is language support for concurrency. A number of languages have been designed to support concurrency, beginning with PL/I in the mid-1960s and including the contemporary languages Ada 95, Java, C#, F#, Python, and Ruby.[1]

1. In the cases of Python and Ruby, programs are interpreted, so there only can be logical concurrency. Even if the machine has multiple processors, these programs cannot make use of more than one.

13.2.3 Design Issues

The most important design issues for language support for concurrency have already been discussed at length: competition and cooperation synchronization. In addition to these, there are several design issues of secondary importance. Prominent among them is how an application can influence task scheduling. Also, there are the issues of how and when tasks start and end their executions, and how and when they are created.

Keep in mind that our discussion of concurrency is intentionally incomplete, and only the most important of the language design issues related to support for concurrency are discussed.

The following sections discuss three alternative approaches to the design issues for concurrency: semaphores, monitors, and message passing.

13.3 Semaphores

A semaphore is a simple mechanism that can be used to provide synchronization of tasks. Although semaphores are an early approach to providing synchronization, they are still used, both in contemporary languages and in library-based concurrency support systems. In the following paragraphs, we describe semaphores and discuss how they can be used for this purpose.

13.3.1 Introduction

In an effort to provide competition synchronization through mutually exclusive access to shared data structures, Edsger Dijkstra devised semaphores in 1965 (Dijkstra, 1968b). Semaphores can also be used to provide cooperation synchronization.

To provide limited access to a data structure, guards can be placed around the code that accesses the structure. A **guard** is a linguistic device that allows the guarded code to be executed only when a specified condition is true. So, a guard can be used to allow only one task to access a particular shared data structure at a time. A semaphore is an implementation of a guard. Specifically, a **semaphore** is a data structure that consists of an integer and a queue that stores task descriptors. A **task descriptor** is a data structure that stores all of the relevant information about the execution state of a task.

An integral part of a guard mechanism is a procedure for ensuring that all attempted executions of the guarded code eventually take place. The typical approach is to have requests for access that occur when access cannot be granted or stored in the task descriptor queue, from which they are later allowed to leave and execute the guarded code. This is the reason a semaphore must have both a counter and a task descriptor queue.

The only two operations provided for semaphores were originally named P and V by Dijkstra, after the two Dutch words *passeren* (to pass) and *vrygeren*

(to release) (Andrews and Schneider, 1983). We will refer to these as *wait* and *release*, respectively, in the remainder of this section.

13.3.2 Cooperation Synchronization

Through much of this chapter, we use the example of a shared buffer used by producers and consumers to illustrate the different approaches to providing cooperation and competition synchronization. For cooperation synchronization, such a buffer must have some way of recording both the number of empty positions and the number of filled positions in the buffer (to prevent buffer underflow and overflow). The counter component of a semaphore can be used for this purpose. One semaphore variable—for example, `emptyspots`—can use its counter to maintain the number of empty locations in a shared buffer used by producers and consumers, and another—say, `fullspots`—can use its counter to maintain the number of filled locations in the buffer. The queues of these semaphores can store the descriptors of tasks that have been forced to wait for access to the buffer. The queue of `emptyspots` can store producer tasks that are waiting for available positions in the buffer; the queue of `fullspots` can store consumer tasks waiting for values to be placed in the buffer.

Our example buffer is designed as an abstract data type in which all data enters the buffer through the subprogram `DEPOSIT`, and all data leaves the buffer through the subprogram `FETCH`. The `DEPOSIT` subprogram needs only to check with the `emptyspots` semaphore to see whether there are any empty positions. If there is at least one, it can proceed with the `DEPOSIT`, which must have the side effect of decrementing the counter of `emptyspots`. If the buffer is full, the caller to `DEPOSIT` must be made to wait in the `emptyspots` queue for an empty spot to become available. When the `DEPOSIT` is complete, the `DEPOSIT` subprogram increments the counter of the `fullspots` semaphore to indicate that there is one more filled location in the buffer.

The `FETCH` subprogram has the opposite sequence of `DEPOSIT`. It checks the `fullspots` semaphore to see whether the buffer contains at least one item. If

it does, an item is removed and the `emptyspots` semaphore has its counter incremented by 1. If the buffer is empty, the calling task is put in the `fullspots` queue to wait until an item appears. When `FETCH` is finished, it must increment the counter of `emptyspots`.

The operations on semaphore types often are not direct—they are done through `wait` and `release` subprograms. Therefore, the `DEPOSIT` operation just described is actually accomplished in part by calls to `wait` and `release`. Note that `wait` and `release` must be able to access the task-ready queue.

The `wait` semaphore subprogram is used to test the counter of a given semaphore variable. If the value is greater than zero, the caller can carry out its operation. In this case, the counter value of the semaphore variable is decremented to indicate that there is now one fewer of whatever it counts. If the value of the counter is zero, the caller must be placed on the waiting queue of the semaphore variable, and the processor must be given to some other ready task.

The `release` semaphore subprogram is used by a task to allow some other task to have one of whatever the counter of the specified semaphore variable counts. If the queue of the specified semaphore variable is empty, which means no task is waiting, `release` increments its counter (to indicate there is one more of whatever is being controlled that is now available). If one or more tasks are waiting, `release` moves one of them from the semaphore queue to the ready queue.

The following are concise pseudocode descriptions of `wait` and `release`:

```
wait(aSemaphore)

if aSemaphore's counter > 0 then

    decrement aSemaphore's counter

else

    put the caller in aSemaphore's queue

    attempt to transfer control to some ready task
```

(if the task-ready queue is empty, deadlock occurs)

end if

`release(aSemaphore)`

if `aSemaphore`'s queue is empty `(no task is waiting)` **then**

increment `aSemaphore`'s counter

else

put the calling task in the task-ready queue

transfer control to a task from `aSemaphore`'s queue

end

We can now present an example program that implements cooperation synchronization for a shared buffer. In this case, the shared buffer stores integer values and is a logically circular structure. It is designed for use by possibly multiple producer and consumer tasks.

The following pseudocode shows the definition of the producer and consumer tasks. Two semaphores are used to ensure against buffer underflow or overflow, thus providing cooperation synchronization. Assume that the buffer has length `BUFLEN`, and the routines that actually manipulate it already exist as `FETCH` and `DEPOSIT`. Accesses to the counter of a semaphore are specified by dot notation. For example, if `fullspots` is a semaphore, its counter is referenced by `fullspots.count`.

```
semaphore fullspots, emptyspots;
fullspots.count = 0;
emptyspots.count = BUFLEN;
task producer;
  loop
  -- produce VALUE --
  wait(emptyspots);     { wait for a space }
  DEPOSIT(VALUE);
  release(fullspots);   { increase filled spaces }
  end loop;
end producer;
```

```
task consumer;
   loop
   wait(fullspots);     { make sure it is not empty }
   FETCH(VALUE);
   release(emptyspots); { increase empty spaces }
   -- consume VALUE --
   end loop
end consumer;
```

The semaphore `fullspots` causes the `consumer` task to be queued to wait for a buffer entry if it is currently empty. The semaphore `emptyspots` causes the `producer` task to be queued to wait for an empty space in the buffer if it is currently full.

13.3.3 Competition Synchronization

Our buffer example does not provide competition synchronization. Access to the structure can be controlled with an additional semaphore. This semaphore need not count anything but can simply indicate with its counter whether the buffer is currently being used. The `wait` statement allows the access only if the semaphore's counter has the value `1`, which indicates that the shared buffer is not currently being accessed. If the semaphore's counter has a value of `0`, there is a current access taking place, and the task is placed in the queue of the semaphore. Notice that the semaphore's counter must be initialized to `1`. The queues of semaphores must always be initialized to empty before use of the queue can begin.

A semaphore that requires only a binary-valued counter, like the one used to provide competition synchronization in the following example, is called a **binary semaphore**.

The example pseudocode that follows illustrates the use of semaphores to provide both competition and cooperation synchronization for a concurrently accessed shared buffer. The `access` semaphore is used to ensure mutually exclusive access to the buffer. Remember that there may be more than one producer and more than one consumer.

```
semaphore access, fullspots, emptyspots;
access.count = 1;
fullspots.count = 0;
emptyspots.count = BUFLEN;
task producer;
  loop
  -- produce VALUE --
  wait(emptyspots);      { wait for a space }
  wait(access);          { wait for access }
  DEPOSIT(VALUE);
  release(access);       { relinquish access }
  release(fullspots);    { increase filled spaces }
  end loop;
end producer;
task consumer;
  loop
  wait(fullspots);      { make sure it is not empty }
  wait(access);         { wait for access }
  FETCH(VALUE);
  release(access);      { relinquish access }
  release(emptyspots);  { increase empty spaces }
  -- consume VALUE --
  end loop
end consumer;
```

A brief look at this example may lead one to believe that there is a problem. Specifically, suppose that while a task is waiting at the `wait(access)` call in `consumer`, another task takes the last value from the shared buffer. Fortunately, this cannot happen, because the `wait(fullspots)` reserves a value in the buffer for the task that calls it by decrementing the `fullspots` counter.

There is one crucial aspect of semaphores that thus far has not been discussed. Recall the earlier description of the problem of competition synchronization: Operations on shared data must not overlap. If a second operation begins while an earlier operation is still in progress, the shared data can become corrupted. A semaphore is itself a shared data object, so the operations on semaphores are also susceptible to the same problem. It is therefore essential that semaphore operations be uninterruptible. Many computers have uninterruptible instructions that were designed specifically for semaphore operations. If such instructions are not available, then using semaphores to provide competition synchronization is a serious problem with no simple solution.

13.3.4 Evaluation

Using semaphores to provide cooperation synchronization creates an unsafe programming environment. There is no way to check statically for the correctness of their use, which depends on the semantics of the program in which they appear. In the buffer example, leaving out the `wait(emptyspots)` statement of the `producer` task would result in buffer overflow. Leaving out the `wait(fullspots)` statement of the `consumer` task would result in buffer underflow. Leaving out either of the releases would result in deadlock. These are cooperation synchronization failures.

The reliability problems that semaphores cause in providing cooperation synchronization also arise when using them for competition synchronization. Leaving out the `wait(access)` statement in either task can cause insecure access to the buffer. Leaving out the `release(access)` statement in either task results in deadlock. These are competition synchronization failures. Noting the danger in using semaphores, Per Brinch Hansen (1973) wrote, “The semaphore is an elegant synchronization tool for an ideal programmer who never makes mistakes.” Unfortunately, ideal programmers are rare.

13.4 Monitors

One solution to some of the problems of semaphores in a concurrent environment is to encapsulate shared data structures with their operations and hide their representations—that is, to make shared data structures abstract data types with some special restrictions. This solution can provide competition synchronization without semaphores by transferring responsibility for synchronization to the run-time system.

13.4.1 Introduction

When the concepts of data abstraction were being formulated, the people involved in that effort applied the same concepts to shared data in concurrent programming environments to produce monitors. According to Per Brinch Hansen (Brinch Hansen, 1977, p. xvi), Edsger Dijkstra suggested in 1971 that all synchronization operations on shared data be gathered into a single program unit. Brinch Hansen (1973) formalized this concept in the environment of operating systems. The following year, Hoare (1974) named these structures *monitors*.

The first programming language to incorporate monitors was Concurrent Pascal (Brinch Hansen, 1975). Modula (Wirth, 1977), CSP/k (Holt et al., 1978), and Mesa (Mitchell et al., 1979) also provide monitors. Among contemporary languages, monitors are supported by Ada, Java, and C#, all of which are discussed later in this chapter.

13.4.2 Competition Synchronization

One of the most important features of monitors is that shared data is resident in the monitor rather than in any of the client units. The programmer does not

synchronize mutually exclusive access to shared data through the use of semaphores or other mechanisms. Because the access mechanisms are part of the monitor, implementation of a monitor can be made to guarantee synchronized access by allowing only one access at a time. Calls to monitor procedures are implicitly blocked and stored in a queue if the monitor is busy at the time of the call.

13.4.3 Cooperation Synchronization

Although mutually exclusive access to shared data is intrinsic with a monitor, cooperation between processes is still the task of the programmer. In particular, the programmer must guarantee that a shared buffer does not experience underflow or overflow. Different languages provide different ways of programming cooperation synchronization, all of which are related to semaphores.

A figure depicting a program containing four tasks and a monitor that provides synchronized access to a concurrently shared buffer is shown in Figure 13.3. In this figure, the interface to the monitor is shown as the two boxes labeled `insert` and `remove` (for the insertion and removal of data). The monitor appears exactly like an abstract data type—a data structure with limited access—which is what a monitor is.

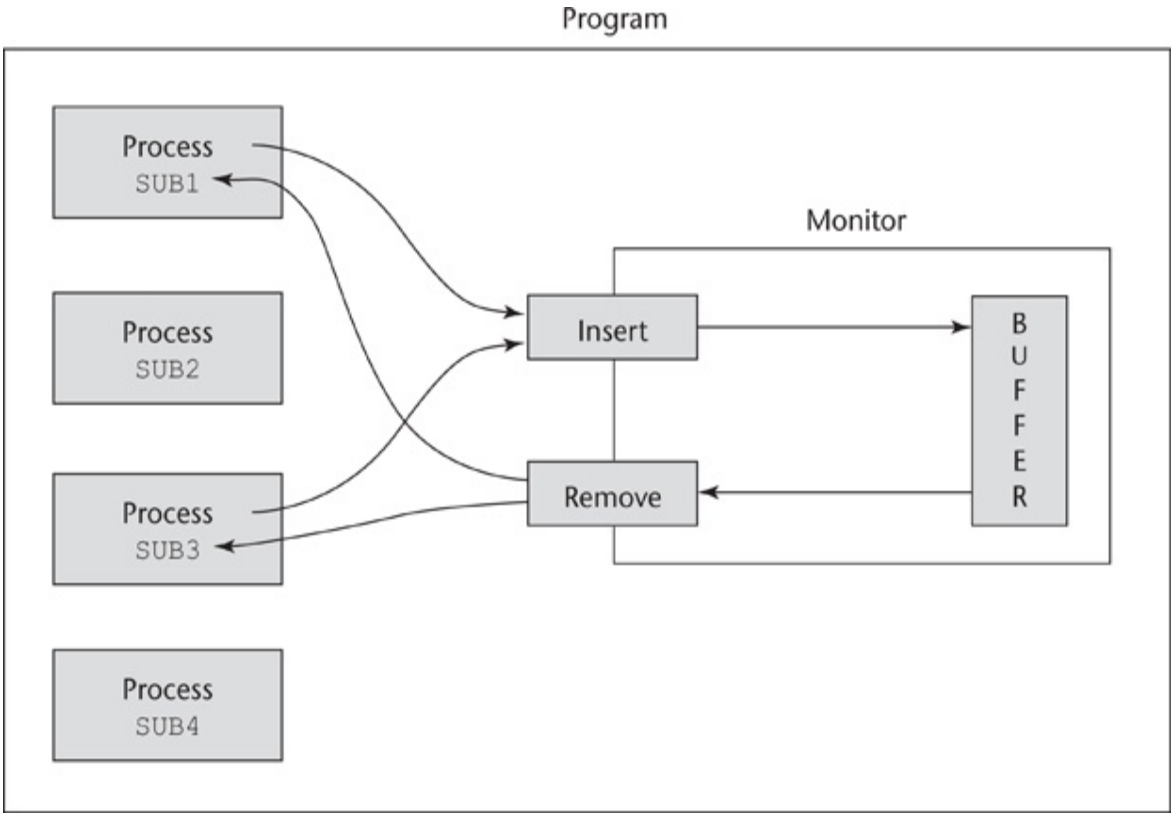

Figure 13.3 A program using a monitor to control access to a shared buffer

Figure 13.3 Full Alternative Text

13.4.4 Evaluation

Monitors are a better way to provide competition synchronization than are semaphores, primarily because of the problems of semaphores, as discussed in Section 13.3. The cooperation synchronization is still a problem with monitors, as will be clear when Ada and Java implementations of monitors are discussed in the following sections.

Semaphores and monitors are equally powerful at expressing concurrency control—semaphores can be used to implement monitors and monitors can be used to implement semaphores.

Ada provides two ways to implement monitors. Ada 83 includes a general tasking model that can be used to support monitors. Ada 95 added a cleaner and more efficient way of constructing monitors, called *protected objects*. Both of these approaches use message passing as a basic model for supporting concurrency. The message-passing model allows concurrent units to be distributed, which monitors do not allow. Message passing is described in Section 13.5; Ada support for message passing is discussed in Section 13.6.

In Java, a monitor can be implemented in a class designed as an abstract data type, with the shared data being the type. Accesses to objects of the class are controlled by adding the **`synchronized`** modifier to the access methods. An example of a monitor for the shared buffer written in Java is given in Section 13.7.4.

C# has a predefined class, `Monitor`, which is designed for implementing monitors.

13.5 Message Passing

This section introduces the fundamental concept of message passing in concurrency. Note that this concept of message passing is unrelated to the message passing used in object-oriented programming to enact methods.

13.5.1 Introduction

The first efforts to design languages that provide the capability for message passing among concurrent tasks were those of Brinch Hansen (1978) and Hoare (1978). These pioneer developers of message passing also developed a technique for handling the problem of what to do when multiple simultaneous requests were made by other tasks to communicate with a given task. It was decided that some form of nondeterminism was required to provide fairness in choosing which among those requests would be taken first. This fairness can be defined in various ways, but in general, it means that all requesters are provided an equal chance of communicating with a given task (assuming that every requester has the same priority). Nondeterministic constructs for statement-level control, called *guarded commands*, were introduced by Dijkstra (1975). Guarded commands are discussed in Chapter 8. Guarded commands are the basis of the construct designed for controlling message passing.

13.5.2 The Concept of Synchronous Message Passing

Message passing can be either synchronous or asynchronous. Here, we describe synchronous message passing. The basic concept of synchronous message passing is that tasks are often busy, and when busy, they cannot be interrupted by other units. Suppose task A and task B are both in execution, and A wishes to send a message to B. Clearly, if B is busy, it is not desirable to

allow another task to interrupt it. That would disrupt B's current processing. Furthermore, messages usually cause associated processing in the receiver, which might not be sensible if other processing is incomplete. The alternative is to provide a linguistic mechanism that allows a task to specify to other tasks when it is ready to receive messages. This approach is somewhat like an executive who instructs his or her secretary to hold all incoming calls until another activity, perhaps an important conversation, is completed. Later, when the current conversation is complete, the executive tells the secretary that he or she is now willing to talk to one of the callers who has been placed on hold.

A task can be designed so that it can suspend its execution at some point, either because it is idle or because it needs information from another unit before it can continue. This is like a person who is waiting for an important call. In some cases, there is nothing else to do but sit and wait. However, if task A is waiting for a message at the time task B sends that message, the message can be transmitted. This actual transmission of the message is called a **rendezvous**. Note that a rendezvous can occur only if both the sender and receiver want it to happen. During a rendezvous, the information of the message can be transmitted in either or both directions.

Both cooperation and competition synchronization of tasks can be conveniently handled with the message-passing model, as described in the following section.

13.6 Ada Support for Concurrency

This section describes the support for concurrency provided by Ada. Ada 83 supports only synchronous message passing.

13.6.1 Fundamentals

The Ada design for tasks is partially based on the work of Brinch Hansen and Hoare in that message passing is the design basis and nondeterminism is used to choose among the tasks that have sent messages.

The full Ada tasking model is complex, and the following discussion of it is limited. The focus here will be on the Ada version of the synchronous message-passing mechanism.

Ada tasks can be more active than monitors. Monitors are passive entities that provide management services for the shared data they store. They provide their services, though only when those services are requested. When used to manage shared data, Ada tasks can be thought of as managers that can reside with the resource they manage. They have several mechanisms, some deterministic and some nondeterministic, that allow them to choose among competing requests for access to their resources.

There are two syntactic parts to an Ada task—a specification part and a body part—both with the same name. The interface of a task is its entry points or locations where it can accept messages from other tasks. Because these entry points are part of its interface, it is natural that they be listed in the specification part of a task. Because a rendezvous can involve an exchange of information, messages can have parameters; therefore, task entry points must also allow parameters, which must also be described in the specification part. In appearance, a task specification is similar to the package specification for an abstract data type.

As an example of an Ada task specification, consider the following code,

which includes a single entry point named `Entry_1`, which has an in-mode parameter:

```
task Task_Example is
  entry Entry_1(Item : in Integer);
end Task_Example;
```

A task body must include some syntactic form of the entry points that correspond to the **`entry`** clauses in that task's specification part. In Ada, these task body entry points are specified by clauses that are introduced by the **`accept`** reserved word. An **`accept` clause** is defined as the range of statements beginning with the **`accept`** reserved word and ending with the matching **`end`** reserved word. **`accept`** clauses are themselves relatively simple, but other constructs in which they can be embedded can make their semantics complex. A simple **`accept`** clause has the following form:

```
accept entry_name (formal parameters) do
  ...
end entry_name;
```

The **`accept`** entry name matches the name in an **`entry`** clause in the associated task specification part. The optional parameters provide the means of communicating data between the caller and the called task. The statements between the **`do`** and the **`end`** define the operations that take place during the rendezvous. These statements are together called the **`accept` clause body**. During the actual rendezvous, the sender task is suspended.

Whenever an **`accept`** clause receives a message that it is not willing to accept, for whatever reason, the sender task must be suspended until the **`accept`** clause in the receiver task is ready to accept the message. Of course, the **`accept`** clause must also remember the sender tasks that have sent messages that were not accepted. For this purpose, each **`accept`** clause in a task has a queue associated with it that stores a list of other tasks that have unsuccessfully attempted to communicate with it.

The following is the skeletal body of the task whose specification was given previously:

```
task body Task_Example is
  begin
```

```
  loop
    accept Entry_1(Item : in Integer) do
      ...
    end Entry_1;
  end loop;
  end Task_Example;
```

The **accept** clause of this task body is the implementation of the **entry** named `Entry_1` in the task specification. If the execution of `Task_Example` begins and reaches the `Entry_1` **accept** clause before any other task sends a message to `Entry_1`, `Task_Example` is suspended. If another task sends a message to `Entry_1` while `Task_Example` is suspended at its **accept**, a rendezvous occurs and the **accept** clause body is executed. Then, because of the loop, execution proceeds back to the **accept**. If no other task has sent a message to `Entry_1`, execution is again suspended to wait for the next message.

A rendezvous can occur in two basic ways in this simple example. First, the receiver task, `Task_Example`, can be waiting for another task to send a message to the `Entry_1` entry. When the message is sent, the rendezvous occurs. This is the situation described earlier. Second, the receiver task can be busy with one rendezvous, or with some other processing not associated with a rendezvous, when another task attempts to send a message to the same entry. In that case, the sender is suspended until the receiver is free to accept that message in a rendezvous. If several messages arrive while the receiver is busy, the senders are queued to wait their turn for a rendezvous.

The two rendezvous just described are illustrated with the timeline diagrams in Figure 13.4.

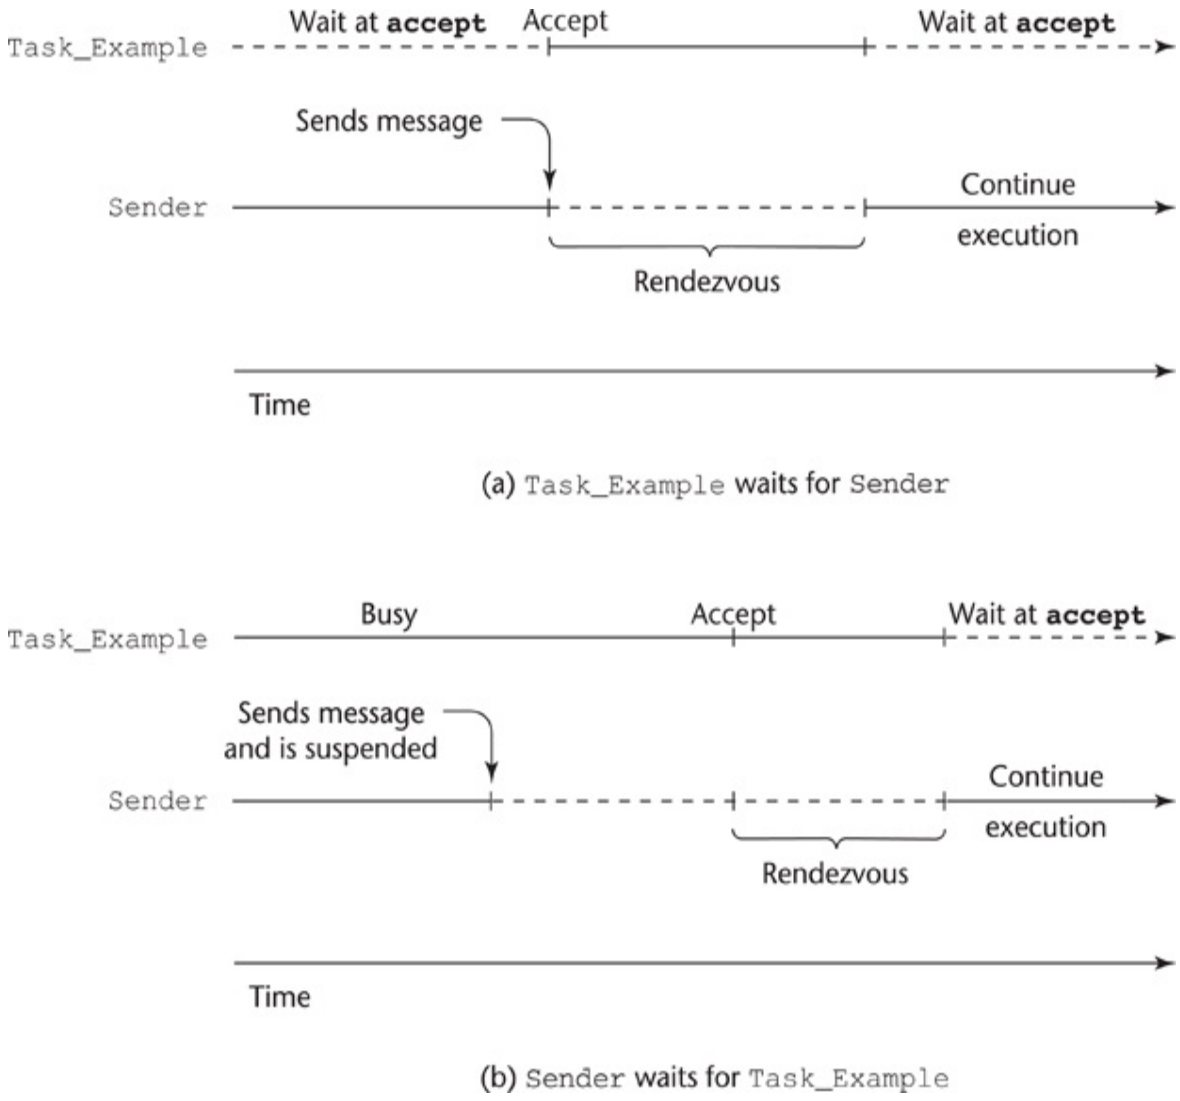

Figure 13.4 Two ways a rendezvous with `Task_Example` can occur

Figure 13.4 Full Alternative Text

Tasks need not have entry points. Such tasks are called **actor tasks** because they do not wait for a rendezvous in order to do their work. Actor tasks can rendezvous with other tasks by sending them messages. In contrast to actor

tasks, a task can have **`accept`** clauses but not have any code outside those **`accept`** clauses, so it can only react to other tasks. Such a task is called a **server task**.

An Ada task that sends a message to another task must know the entry name in that task. However, the opposite is not true: A task entry need not know the name of the task from which it will accept messages. This asymmetry is in contrast to the design of the language known as CSP, or Communicating Sequential Processes (Hoare, 1978). In CSP, which also uses the message--passing model of concurrency, tasks accept messages only from explicitly named tasks. The disadvantage of this is that libraries of tasks cannot be built for general use.

The usual graphical method of describing a rendezvous in which task A sends a message to task B is shown in Figure 13.5.

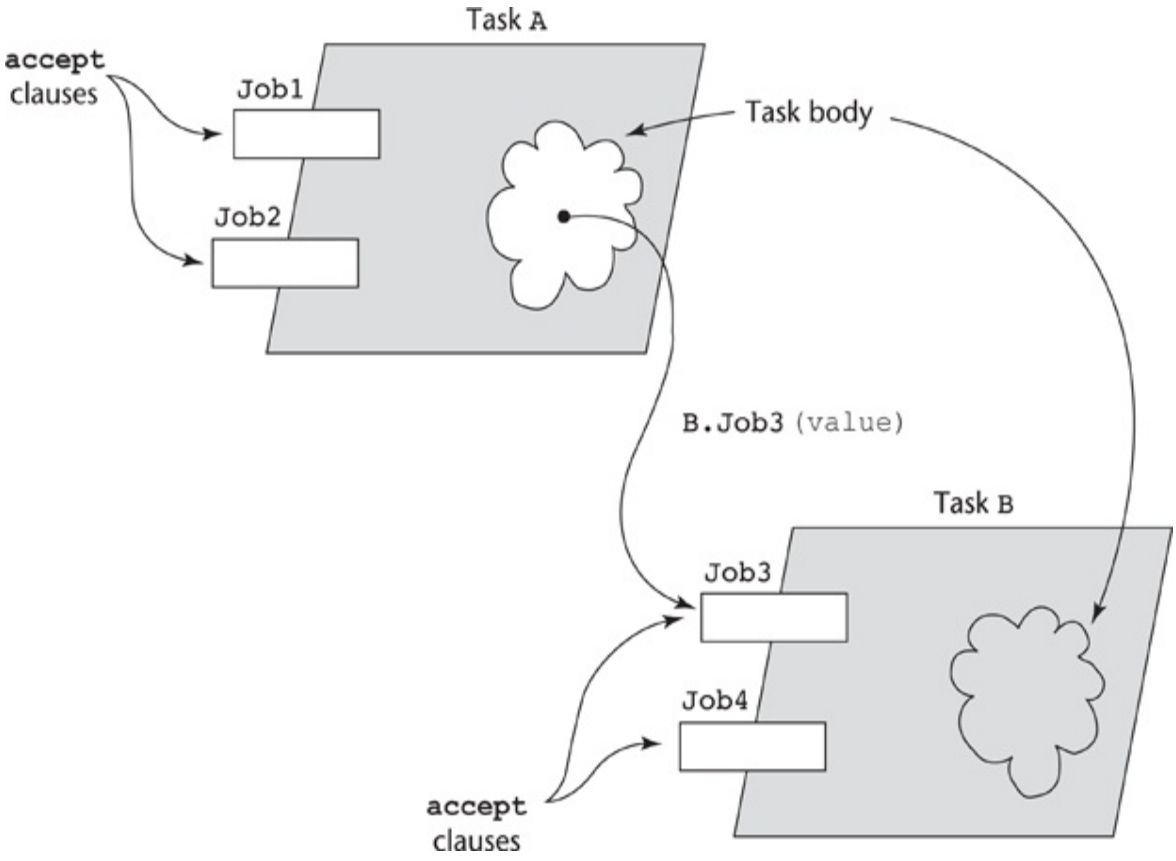

Figure 13.5 Graphical -

representation of a rendezvous caused by a message sent from task `A` to task `B`

Figure 13.5 Full Alternative Text

Tasks are declared in the declaration part of a package, subprogram, or block. Statically created tasks2 begin executing at the same time as the statements in the code to which that declarative part is attached. For example, a task declared in a main program begins execution at the same time as the first statement in the code body of the main program. Task termination, which is a complex issue, is discussed later in this section.

2. Tasks can also be dynamically created, but such tasks are not covered here.

Tasks may have any number of entries. The order in which the associated **`accept`** clauses appear in the task dictates the order in which messages can be accepted. If a task has more than one entry point and requires them to be able to receive messages in any order, the task uses a **`select`** statement to enclose the entries. For example, suppose a task models the activities of a bank teller, who must serve customers at a walk-up station inside the bank and also serve customers at a drive-up window. The following skeletal teller task illustrates a **`select`** construct:

```
task body Teller is
begin
  loop
    select
      accept Drive_Up(formal parameters) do
        ...
      end Drive_Up;
      ...
    or
      accept Walk_Up(formal parameters) do
        ...
      end Walk_Up;
      ...
```

```
    end select;
  end loop;
end Teller;
```

In this task, there are two **accept** clauses, Walk_Up and Drive_Up, each of which has an associated queue. The action of the **select**, when it is executed, is to examine the queues associated with the two **accept** clauses. If one of the queues is empty, but the other contains at least one waiting message (customer), the **accept** clause associated with the waiting message or messages has a rendezvous with the task that sent the first message that was received. If both **accept** clauses have empty queues, the **select** waits until one of the entries is called. If both **accept** clauses have nonempty queues, one of the **accept** clauses is nondeterministically chosen to have a rendezvous with one of its callers. The loop forces the **select** statement to be executed repeatedly, forever.

The **end** of the **accept** clause marks the end of the code that assigns or references the formal parameters of the **accept** clause. The code, if there is any, between an **accept** clause and the next **or** (or the **end select**, if the **accept** clause is the last one in the **select**) is called the **extended accept clause**. The extended **accept** clause is executed only after the associated (immediately preceding) **accept** clause is executed. This execution of the extended **accept** clause is not part of the rendezvous and can take place concurrently with the execution of the calling task. The sender is suspended during the rendezvous, but it is put back in the ready queue when the end of the **accept** clause is reached. If an **accept** clause has no formal parameters, the **do-end** is not required, and the **accept** clause can consist entirely of an extended **accept** clause. Such an **accept** clause would be used exclusively for synchronization. Extended **accept** clauses are illustrated in the Buf_Task task in Section 13.6.3.

13.6.2 Cooperation Synchronization

Each **accept** clause can have a guard attached, in the form of a **when** clause,

that can delay rendezvous. For example,

```
when not Full(Buffer) =>
  accept Deposit(New_Value) do
    ...
  end
```

An **accept** clause with a **when** clause is either open or closed. If the Boolean expression of the **when** clause is currently true, that **accept** clause is called **open**; if the Boolean expression is false, the **accept** clause is called **closed**. An **accept** clause that does not have a guard is always open. An open **accept** clause is available for rendezvous; a closed **accept** clause cannot rendezvous.

Suppose there are several guarded **accept** clauses in a **select** clause. Such a **select** clause is usually placed in an infinite loop. The loop causes the **select** clause to be executed repeatedly, with each **when** clause evaluated on each repetition. Each repetition causes a list of open **accept** clauses to be constructed. If exactly one of the open clauses has a nonempty queue, a message from that queue is taken and a rendezvous takes place. If more than one of the open **accept** clauses has nonempty queues, one queue is chosen nondeterministically, a message is taken from that queue, and a rendezvous takes place. If the queues of all open clauses are empty, the task waits for a message to arrive at one of those **accept** clauses, at which time a rendezvous will occur. If a **select** is executed and every **accept** clause is closed, a run-time exception or error results. This possibility can be avoided either by making sure one of the **when** clauses is always true or by adding an **else** clause in the **select**. An **else** clause can include any sequence of statements, except an **accept** clause.

A **select** clause may have a special statement, **terminate**, that is selected only when it is open and no other **accept** clause is open. A **terminate** clause, when selected, means that the task is finished with its job but is not yet terminated. Task termination is discussed later in this section.

13.6.3 Competition Synchronization

The features described so far provide for cooperation synchronization and communication among tasks. Next, we discuss how mutually exclusive access to shared data structures can be enforced in Ada.

If access to a data structure is to be controlled by a task, then mutually exclusive access can be achieved by declaring the data structure within a task. The semantics of task execution usually guarantees mutually exclusive access to the structure, because only one **accept** clause in the task can be active at a given time. The only exceptions to this occur when tasks are nested in procedures or other tasks. For example, if a task that defines a shared data structure has a nested task, that nested task can also access the shared structure, which could destroy the integrity of the data. Thus, tasks that are meant to control access to a shared data structure should not define tasks.

The following is an example of an Ada task that implements a monitor for a buffer. The buffer behaves very much like the buffer in Section 13.3, in which synchronization is controlled with semaphores.

```
task Buf_Task is
   entry Deposit(Item : in Integer);
   entry Fetch(Item : out Integer);
end Buf_Task;
task body Buf_Task is
  Bufsize : constant Integer := 100;
  Buf   :  array (1..Bufsize) of Integer;
  Filled : Integer range 0..Bufsize := 0;
  Next_In,
  Next_Out : Integer range 1..Bufsize := 1;
begin
  loop
    select
      when Filled < Bufsize =>
         accept Deposit(Item : in Integer) do
           Buf(Next_In) := Item;
         end Deposit;
        Next_In := (Next_In mod Bufsize) + 1;
        Filled := Filled + 1;
    or
      when Filled > 0 =>
        accept Fetch(Item : out Integer) do
          Item := Buf(Next_Out);
        end Fetch;
        Next_Out := (Next_Out mod Bufsize) + 1;
```

```
        Filled := Filled - 1;
    end select;
   end loop;
end Buf_Task;
```

In this example, both **accept** clauses are extended. These extended clauses can be executed concurrently with the tasks that called the associated **accept** clauses.

The tasks for a producer and a consumer that could use `Buf_Task` have the following form:

```
task Producer;
task Consumer;
task body Producer is
  New_Value : Integer;
begin
  loop
    -- produce New_Value --
    Buf_Task.Deposit(New_Value);
  end loop;
end Producer;
task body Consumer is
  Stored_Value : Integer;
begin
  loop
    Buf_Task.Fetch(Stored_Value);
    -- consume Stored_Value --
  end loop;
end Consumer;
```

13.6.4 Protected Objects

As we have seen, access to shared data can be controlled by enclosing the data in a task and allowing access only through task entries, which implicitly provide competition synchronization. One problem with this method is that it is difficult to implement the rendezvous mechanism efficiently. Ada 95 protected objects provide an alternative method of providing competition synchronization that need not involve the rendezvous mechanism.

A protected object is not a task; it is more like a monitor, as described in

Section 13.4. Protected objects can be accessed either by protected subprograms or by entries that are syntactically similar to the **accept** clauses in tasks.3 The protected subprograms can be either protected procedures, which provide mutually exclusive read-write access to the data of the protected object, or protected functions, which provide concurrent read-only access to that data. Entries differ from protected subprograms in that they can have guards.

3. Entries in protected object bodies use the reserved word `entry`, rather than the `accept` used in task bodies.

Within the body of a protected procedure, the current instance of the enclosing protected unit is defined to be a variable; within the body of a protected function, the current instance of the enclosing protected unit is defined to be a constant, which allows concurrent read-only access.

Entry calls to a protected object provide synchronous communication with one or more tasks using the same protected object. These entry calls provide access similar to that provided to the data enclosed in a task.

The buffer problem that is solved with a task in the previous subsection can be more simply solved with a protected object. Note that this example does not include protected subprograms.

```
protected Buffer is
  entry Deposit(Item : in Integer);
  entry Fetch(Item : out Integer);
private
  Bufsize : constant Integer := 100;
  Buf   : array  (1..Bufsize) of Integer;
  Filled : Integer range 0..Bufsize := 0;
  Next_In,
  Next_Out : Integer range 1..Bufsize := 1;
  end Buffer;
protected body Buffer is
  entry Deposit(Item : in Integer)
     when Filled < Bufsize is
    begin
    Buf(Next_In) := Item;
    Next_In := (Next_In mod Bufsize) + 1;
    Filled := Filled + 1;
    end Deposit;
```

```
  entry Fetch(Item : out Integer) when Filled > 0 is
    begin Item := Buf(Next_Out);
    Next_Out := (Next_Out mod Bufsize) + 1;
    Filled := Filled - 1;
    end Fetch;
end Buffer;
```

13.6.5 Evaluation

Using the general message-passing model of concurrency to construct monitors is like using Ada packages to support abstract data types—both are tools that are more general than is necessary. Protected objects are a better way to provide synchronized access to shared data.

In the absence of distributed processors with independent memories, the choice between monitors and tasks with message passing as a means of implementing synchronized access to shared data in a concurrent environment is somewhat a matter of taste. However, in the case of Ada, protected objects are clearly better than tasks for supporting concurrent access to shared data. Not only is the code simpler; it is also much more efficient.

For distributed systems, message passing is a better model for concurrency, because it naturally supports the concept of separate processes executing in parallel on separate processors.

13.7 Java Threads

The concurrent units in Java are methods named `run`, whose code can be in concurrent execution with other such methods (of other objects) and with the `main` method. The process in which the `run` methods execute is called a **thread**. Java's threads are lightweight tasks, which means that they all run in the same address space. This is different from Ada tasks, which are heavyweight threads (they run in their own address spaces).4 One important result of this difference is that threads require far less overhead than Ada's tasks.

4. Actually, although Ada tasks behave as if they were heavyweight tasks, in some cases, they are now implemented as threads. This is sometimes done using libraries, such as the IBM Rational Apex Native POSIX Threading Library.

There are two ways to define a class with a `run` method. One of these is to define a subclass of the predefined class `Thread` and override its `run` method. However, if the new subclass has a necessary natural parent, then defining it as a subclass of `Thread` obviously will not work. In these situations, we define a subclass that inherits from its natural parent and implements the `Runnable` interface. `Runnable` provides the `run` method protocol, so any class that implements `Runnable` must define `run`. An object of the class that implements `Runnable` is passed to the `Thread` constructor. So, this approach still requires a `Thread` object, as will be seen in the example in Section 13.7.5.

In Ada, tasks can be either actors or servers and tasks communicate with each other through **`accept`** clauses. Java `run` methods are all actors and there is no mechanism for them to communicate with each other, except for the `join` method (see Section 13.7.1) and through shared data.

Java threads is a complex topic—this section only provides an introduction to its simplest but most useful parts.

13.7.1 The Thread Class

The `Thread` class is not the natural parent of any other classes. It provides some services for its subclasses, but it is not related in any natural way to their computational purposes. `Thread` is the only class available for creating concurrent Java programs. As previously stated, Section 13.7.5 will briefly discuss the use of the `Runnable` interface.

The `Thread` class includes five constructors and a collection of methods and constants. The `run` method, which describes the actions of the thread, is always overridden by subclasses of `Thread`. The `start` method of `Thread` starts its thread as a concurrent unit by calling its `run` method.5 The call to `start` is unusual in that control returns immediately to the caller, which then continues its execution, in parallel with the newly started `run` method.

5. Calling the `run` method directly does not always work, because initialization that is sometimes required is included in the `start` method.

Following is a skeletal subclass of `Thread` and a code fragment that creates an object of the subclass and starts the `run` method's execution in the new thread:

```
class MyThread extends Thread {
  public void run() { . . . }
}
. . .
Thread myTh = new MyThread();
myTh.start();
```

When a Java application program begins execution, a new thread is created (in which the **`main`** method will run) and **`main`** is called. Therefore, all Java application programs run in threads.

When a program has multiple threads, a scheduler must determine which thread or threads will run at any given time. In many cases, there is only a single processor available, so only one thread actually runs at a time. It is difficult to give a precise description of how the Java scheduler works, because the different implementations (Solaris, Windows, and so on) do not

necessarily schedule threads in exactly the same way. Typically, however, the scheduler gives equal-size time slices to each ready thread in round-robin fashion, assuming all of these threads have the same priority. Section 13.7.2 describes how different priorities can be given to different threads.

The `Thread` class provides several methods for controlling the execution of threads. The `yield` method, which takes no parameters, is a request from the running thread to surrender the processor voluntarily.6 The thread is put immediately in the task-ready queue, making it ready to run. The scheduler then chooses the highest-priority thread from the task-ready queue. If there are no other ready threads with priority higher than the one that just yielded the processor, it may also be the next thread to get the processor.

6. The `yield` method is actually defined to be a "suggestion" to the scheduler, which it may or may not follow (though it usually does).

The `sleep` method has a single parameter, which is the integer number of milliseconds that the caller of `sleep` wants the thread to be blocked. After the specified number of milliseconds has passed, the thread will be put in the task-ready queue. Because there is no way to know how long a thread will be in the task-ready queue before it runs, the parameter to `sleep` is the minimum amount of time the thread will *not* be in execution. The `sleep` method can throw an `InterruptedException`, which must be handled in the method that calls `sleep`. Exceptions are described in detail in Chapter 14.

The `join` method is used to force a method to delay its execution until the `run` method of another thread has completed its execution. `join` is used when the processing of a method cannot continue until the work of the other thread is complete. For example, we might have the following `run` method:

```
public void run() {
  . . .
  Thread myTh = new Thread();
  myTh.start();
  // do part of the computation of this thread
  myTh.join();  // Wait for myTh to complete
  // do the rest of the computation of this thread
}
```

The `join` method puts the thread that calls it in the blocked state, which can

be ended only by the completion of the thread on which `join` was called. If that thread happens to be blocked, there is the possibility of deadlock. To prevent this, `join` can be called with a parameter, which is the time limit in milliseconds of how long the calling thread will wait for the called thread to complete. For example, the following call to `join` will cause the calling thread to wait two seconds for `myTh` to complete. If it has not completed its execution after two seconds have passed, the calling thread is put back in the ready queue, which means that it will continue its execution as soon as it is scheduled.

```
myTh.join(2000);
```

Early versions of Java included three more `Thread` methods: `stop`, `suspend`, and `resume`. All three of these have been deprecated because of safety problems. The `stop` method is sometimes overridden with a simple method that destroys the thread by setting its reference variable to **`null`**.

The normal way a `run` method ends its execution is by reaching the end of its code. However, in many cases, threads run until told to terminate. Regarding this, there is the question of how a thread can determine whether it should continue or end. The `interrupt` method is one way to communicate to a thread that it should stop. This method does not stop the thread; rather, it sends the thread a message that actually just sets a bit in the thread object, which can be checked by the thread. The bit is checked with the predicate method, `isInterrupted`. This is not a complete solution, because the thread one is attempting to interrupt may be sleeping or waiting at the time the `interrupt` method is called, which means that it will not be checking to see if it has been interrupted. For these situations, the `interrupt` method also throws an exception, `InterruptedException`, which also causes the thread to awaken (from sleeping or waiting). So, a thread can periodically check to see whether it has been interrupted and if so, whether it can terminate. The thread cannot miss the interrupt, because if it was asleep or waiting when the interrupt occurred, it will be awakened by the interrupt. Actually, there are more details to the actions and uses of `interrupt`, but they are not covered here (Arnold et al., 2006).

13.7.2 Priorities

The priorities of threads need not all be the same. A thread's default priority initially is the same as the thread that created it. If `main` creates a thread, its default priority is the constant `NORM_PRIORITY`, which is usually 5. `Thread` defines two other priority constants, `MAX_PRIORITY` and `MIN_PRIORITY`, whose values are usually 10 and 1, respectively.7 The priority of a thread can be changed with the method `setPriority`. The new priority can be any of the predefined constants or any other number between `MIN_PRIORITY` and `MAX_PRIORITY`. The `getPriority` method returns the current priority of a thread. The priority constants are defined in `Thread`.

7. The number of priorities is implementation dependent, so there may be fewer or more than 10 levels in some implementations.

When there are threads with different priorities, the scheduler's behavior is controlled by those priorities. When the executing thread is blocked or killed or the time slice for it expires, the scheduler chooses the thread from the task-ready queue that has the highest priority. A thread with lower priority will run only if one of higher priority is not in the task-ready queue when the opportunity arises.

13.7.3 Semaphores

The `java.util.concurrent.Semaphore` package defines the `Semaphore` class. Objects of this class implement counting semaphores. A counting semaphore has a counter, but no queue for storing thread descriptors. The `Semaphore` class defines two methods, `acquire` and `release`, which correspond to the `wait` and `release` operations described in Section 13.3.

The basic constructor for `Semaphore` takes one integer parameter, which initializes the semaphore's counter. For example, the following could be used to initialize the `fullspots` and `emptyspots` semaphores for the buffer example of Section 13.3.2:

```
fullspots = new Semaphore(0);
emptyspots = new Semaphore(BUFLEN);
```

The deposit operation of the producer method would appear as follows:

```
emptyspots.acquire();
deposit(value);
fullspots.release();
```

Likewise, the fetch operation of the consumer method would appear as follows:

```
fullspots.acquire();
fetch(value);
emptyspots.release();
```

The `deposit` and `fetch` methods could use the approach used in Section 13.7.4 to provide the competition synchronization required for the accesses to the buffer.

13.7.4 Competition Synchronization

Java methods (but not constructors) can be specified to be **`synchronized`**. A synchronized method called through a specific object must complete its execution before any other synchronized method can run on that object. Competition synchronization on an object is implemented by specifying that the methods that access shared data are synchronized. The synchronized mechanism is implemented as follows: Every Java object has a lock. Synchronized methods must acquire the lock of the object before they are allowed to execute, which prevents other synchronized methods from executing on the object during that time. A synchronized method releases the lock on the object on which it runs when it completes its execution, even if that completion is due to an exception. Consider the following skeletal class definition:

```
class ManageBuf {
  private int [100] buf;
```

```
  . . .
  public synchronized void deposit(int item) { . . . }
  public synchronized int fetch() { . . . }
  . . .
}
```

The two methods defined in `ManageBuf` are both defined to be **`synchronized`**, which prevents them from interfering with each other while executing on the same object, when they are called by separate threads.

An object whose methods are all synchronized is effectively a monitor. Note that an object may have one or more synchronized methods, as well as one or more unsynchronized methods. An unsynchronized method can run on an object at anytime, even during the execution of a synchronized method.

In some cases, the number of statements that deal with the shared data structure is significantly less than the number of other statements in the method in which it resides. In these cases, it is better to synchronize the code segment that changes the shared data structure rather than the whole method. This can be done with a so-called *synchronized statement*, whose general form is as follows:

```
synchronized (expression){
 statements
}
```

The expression in this code must evaluate to an object and the statement can be a single statement or a compound statement. The object is locked during execution of the statement or compound statement, so the statement or compound statement is executed exactly as if it were the body of a synchronized method.

An object that has synchronized methods defined for it must have a queue associated with it that stores the synchronized methods that have attempted to execute on it while it was being operated upon by another synchronized method. Actually, every object has a queue called the **intrinsic condition queue**. These queues are implicitly supplied. When a synchronized method completes its execution on an object, a method that is waiting in the object's intrinsic condition queue, if there is such a method, is put in the task-ready queue.

13.7.5 Cooperation Synchronization

Cooperation synchronization in Java is implemented with the `wait`, `notify`, and `notifyAll` methods, all of which are defined in `Object`, the root class of all Java classes. All classes except `Object` inherit these methods. Every object has a wait list of all of the threads that have called `wait` on the object. The `notify` method is called to tell one waiting thread that an event that it may have been waiting for has occurred. The specific thread that is awakened by `notify` cannot be determined, because the Java Virtual Machine (JVM) chooses one from the wait list of the thread object at random. Because of this, along with the fact that the waiting threads may be waiting for different conditions, the `notifyAll` method is often used, rather than `notify`. The `notifyAll` method awakens all of the threads on the object's wait list by putting them in the task-ready queue.

The methods `wait`, `notify`, and `notifyAll` can be called only from within a synchronized method, because they use the lock placed on an object by such a method. The call to `wait` is always put in a **`while`** loop that is controlled by the condition for which the method is waiting. The **`while`** loop is necessary because the `notify` or `notifyAll` that awakened the thread may have been called because of a change in a condition other than the one for which the thread was waiting. If it was a call to `notifyAll`, there is even a smaller chance that the condition being waited for is now true. Because of the use of `notifyAll`, some other thread may have changed the condition to false since it was last tested.

The `wait` method can throw `InterruptedException`, which is a descendant of `Exception`. Java's exception handling is discussed in Chapter 14. Therefore, any code that calls `wait` must also catch `InterruptedException`. Assuming the condition being waited for is called `theCondition`, the conventional way to use `wait` is as follows:

```
try  {
  while (!theCondition)
    wait();
```

```
  -- Do whatever is needed after theCondition comes true
}
catch(InterruptedException myProblem) { . . . }
```

The following program implements a circular queue for storing **int** values. It illustrates both cooperation and competition synchronization.

```
// Queue
// This class implements a circular queue for storing int
// values. It includes a constructor for allocating and
// initializing the queue to a specified size. It has
// synchronized methods for inserting values into and
// removing values from the queue.
class Queue {
  private int [] que;
  private int nextIn,
              nextOut,
              filled,
              queSize;
  public Queue(int size) {
    que = new int [size];
    filled = 0;
    nextIn = 1;
    nextOut = 1;
    queSize = size;
  }  //** end of Queue constructor
  public synchronized void deposit (int item)
         throws InterruptedException {
    try {
      while (filled == queSize)
        wait();
      que [nextIn] = item;
      nextIn = (nextIn % queSize) + 1;
      filled++;
      notifyAll();
    }  //** end of try clause
    catch(InterruptedException e) {}
  }  //** end of deposit method
  public synchronized int fetch()
      throws InterruptedException {
    int item = 0;
    try {
      while (filled == 0)
        wait();
      item = que [nextOut];
      nextOut = (nextOut % queSize) + 1;
      filled--;
```

```
      notifyAll();
    }  //** end of try clause
    catch(InterruptedException e) {}
    return item;
  }  //** end of fetch method
}  //** end of Queue class
```

Notice that the exception handler (**`catch`**) does nothing here.

Classes to define producer and consumer objects that could use the `Queue` class can be defined as follows:

```
class Producer extends Thread {
  private Queue buffer;
  public Producer(Queue que) {
    buffer = que;
  }
  public void run() {
     int new_item;
     while  (true) {
      //-- Create a new_item
      buffer.deposit(new_item);
    }
  }
}

class Consumer extends Thread {
  private Queue buffer;
  public Consumer(Queue que) {
    buffer = que;
  }
  public void run() {
    int stored_item;
    while (true) {
      stored_item = buffer.fetch();
      //-- Consume the stored_item
    }
  }
}
```

The following code creates a `Queue` object, and a `Producer` and a `Consumer` object, both attached to the `Queue` object, and starts their execution:

```
Queue buff1 = new Queue(100);
Producer producer1 = new Producer(buff1);
Consumer consumer1 = new Consumer(buff1);
```

```
producer1.start();
consumer1.start();
```

We could define one or both of the `Producer` and the `Consumer` as implementations of the `Runnable` interface rather than as subclasses of `Thread`. The only difference is in the first line, which would now appear as follows:

```
class Producer implements Runnable { . . . }
```

To create and run an object of such a class, it is still necessary to create a `Thread` object that is connected to the object. This is illustrated in the following code:

```
Producer producer1 = new Producer(buff1);
Thread producerThread = new Thread(producer1);
producerThread.start();
```

Note that the buffer object is passed to the `Producer` constructor and the `Producer` object is passed to the `Thread` constructor.

13.7.6 Nonblocking Synchronization

Java includes some classes for controlling accesses to certain variables that do not include blocking or waiting. The `java.util.concurrent.atomic` package defines classes that allow certain nonblocking synchronized access to **`int`**, **`long`**, and **`boolean`** primitive type variables, as well as references and arrays. For example, the `AtomicInteger` class defines getter and setter methods, as well as methods for add, increment, and decrement operations. These operations are all atomic; that is, they cannot be interrupted, so locks are not required to guarantee the integrity of the values of the affected variables in a multithreaded program. This is fine-grained synchronization—just a single variable. Most machines now have atomic instructions for these operations on **`int`** and **`long`** types, so they are often easy to implement (implicit locks are not required).

The advantage of nonblocking synchronization is efficiency. A nonblocking access that does not occur during contention will be no slower, and usually faster than one that uses **`synchronized`**. A nonblocking access that occurs during contention definitely will be faster than one that uses **`synchronized`**, because the latter will require suspension and rescheduling of threads.

13.7.7 Explicit Locks

Java 5.0 introduced explicit locks as an alternative to **`synchronized`** method and blocks, which provide implicit locks. The `Lock` interface declares the `lock`, `unlock`, and `tryLock` methods. The predefined `ReentrantLock` class implements the `Lock` interface. To lock a block of code, the following idiom can be used:

```
Lock lock = new ReentrantLock();
. . .
Lock.lock();
try {
   // The code that accesses the shared data
} finally  {
  Lock.unlock();
}
```

This skeletal code creates a `Lock` object and calls the `lock` method on the `Lock` object. Then, it uses a **`try`** block to enclose the critical code. The call to `unlock` is in a **`finally`** clause to guarantee the lock is released, regardless of what happens in the **`try`** block.

There are at least two situations in which explicit locks are used rather than implicit locks: First, if the application needs to try to acquire a lock but cannot wait forever for it, the `Lock` interface includes a method, `tryLock`, that takes a time limit parameter. If the lock is not acquired within the time limit, execution continues at the statement following the call to `tryLock`. Second, explicit locks are used when it is not convenient to have the lock-unlock pairs block structured. Implicit locks are always unlocked at the end of the compound statement in which they are locked. Explicit locks can be unlocked anywhere in the code, regardless of the structure of the program.

One danger of using explicit locks (and is not the case with using implicit locks) is that of omitting the unlock. Implicit locks are implicitly unlocked at the end of the locked block. However, explicit locks stay locked until explicitly unlocked, which can potentially be never.

As stated previously, each object has an intrinsic condition queue, which stores threads waiting for a condition on the object. The `wait`, `notify`, and `notifyAll` methods are the API for an intrinsic condition queue. Because each object can have just one condition queue, a queue may have threads in it waiting for different conditions. For example, the queue for our buffer example `Queue` can have threads waiting for either of two conditions (`filled == queSize` or `filled == 0`). That is the reason why the buffer uses `notifyAll`. (If it used `notify`, only one thread would be awakened, and it might be one that was waiting for a different condition than the one that actually became true.) However, `notifyAll` is expensive to use, because it awakens all threads waiting on an object and all must check their condition to determine which one runs. Furthermore, to check their condition, they must first acquire the lock on the object.

An alternative to using the intrinsic condition queue is the `Condition` interface, which uses a condition queue associated with a `Lock` object. It also declares alternatives to `wait`, `notify`, and `notifyAll` named `await`, `signal`, and `signalAll`. There can be any number of `Condition` objects with one `Lock` object. With `Condition`, `signal`, rather than `signalAll`, can be used, which is both easier to understand and more efficient, in part because it results in fewer context switches.

13.7.8 Evaluation

Java’s support for concurrency is relatively simple but effective. All Java `run` methods are actor tasks and there is no mechanism for communication, except through shared data, as there is among Ada tasks. Because they are heavyweight threads, Ada’s tasks easily can be distributed to different processors; in particular, different processors with different memories, which could be on different computers in different places. These kinds of systems are not possible with Java’s threads.

13.8 C# Threads

Although C#'s threads are loosely based on those of Java, there are significant differences. Following is a brief overview of C#'s threads.

13.8.1 Basic Thread Operations

Rather than just methods named `run`, as in Java, any C# method can run in its own thread. When C# threads are created, they are associated with an instance of a predefined delegate, `ThreadStart`. When execution of a thread is started, its delegate has the address of the method it is supposed to run. So, execution of a thread is controlled through its associated delegate.

A C# thread is created by creating a `Thread` object. The `Thread` constructor must be sent an instantiation of `ThreadStart`, to which must be sent the name of the method that is to run in the thread. For example, we might have

```
public void MyRun1() { . . . }
. . .
Thread myThread = new Thread(new ThreadStart(MyRun1));
```

In this example, we create a thread named `myThread`, whose delegate points to the method `MyRun1`. So, when the thread begins execution it calls the method whose address is in its delegate. In this example, `myThread` is the delegate and `MyRun1` is the method.

Unlike Java, in which all threads are actors, C# has two categories of threads: actors and servers. Actor threads are not called specifically; rather, they are started. Also, the methods that they execute do not take parameters or return values. As with Java, creating a thread does not start its concurrent execution. For actor threads, execution must be requested through a method of the `Thread` class, in this case named `Start`, as in

```
myThread.Start();
```

As in Java, a thread can be made to wait for another thread to finish its execution before continuing, using the similarly named method `Join`. For example, suppose thread `A` has the following call:

```
B.Join();
```

Thread `A` will be blocked until thread `B` exits.

The `Join` method can take an **`int`** parameter, which specifies a time limit in milliseconds that the caller will wait for the thread to finish.

A thread can be suspended for a specified amount of time with `Sleep`, which is a public static method of `Thread`. The parameter to `Sleep` is an integer number of milliseconds. Unlike its Java relative, C#'s `Sleep` does not raise any exceptions, so it need not be called in a **`try`** block.

A thread can be terminated with the `Abort` method, although it does not literally kill the thread. Instead, it throws `ThreadAbortException`, which the thread can catch. When the thread catches this exception, it usually deallocates any resources it allocated, and then ends (by getting to the end of its code).

A server thread runs only when called through its delegate. These threads are called servers because they provide some service when it is requested. Server threads are more interesting than actor threads because they usually interact with other threads and often must have their execution synchronized with other threads.

Recall from Chapter 9, that any C# method can be called indirectly through a delegate. Such calls can be made by treating the delegate object as if it were the name of the method. This was actually an abbreviation for a call to a delegate method named `Invoke`. So, if a delegate object's name is `chgfun1` and the method it references takes one **`int`** parameter, we could call that method with either of the following statements:

```
chgfun1(7);
chgfun1.Invoke(7);
```

These calls are synchronous; that is, when the method is called, the caller is

blocked until the method completes its execution. C# also supports asynchronous calls to methods that execute in threads. When a thread is called asynchronously, the called thread and the caller thread execute concurrently, because the caller is not blocked during the execution of the called thread.

A thread is called asynchronously through the delegate instance method `BeginInvoke`, to which are sent the parameters for the method of the delegate, along with two additional parameters, one of type `AsyncCallback` and the other of type **`object`**. `BeginInvoke` returns an object that implements the `IAsyncResult` interface. The delegate class also defines the `EndInvoke` instance method, which takes one parameter of type `IAsyncResult` and returns the same type that is returned by the method encapsulated in the delegate object. To call a thread asynchronously, we call it with `BeginInvoke`. For now, we will use **`null`** for the last two parameters. Suppose we have the following method declaration and thread definition:

```
public float MyMethod1(int  x);
. . .
Thread myThread = new Thread(new ThreadStart(MyMethod1));
```

The following statement calls `MyMethod` asynchronously:

```
IAsyncResult result = myThread.BeginInvoke(10, null, null);
```

The return value of the called thread is fetched with `EndInvoke` method, which takes as its parameter the object (of type `IAsyncResult`) returned by `BeginInvoke`. `EndInvoke` returns the return value of the called thread. For example, to get the **`float`** result of the call to `MyMethod`, we would use the following statement:

```
float  returnValue = EndInvoke(result);
```

If the caller must continue some work while the called thread executes, it must have a way to determine when the called thread is finished. For this, the `IAsyncResult` interface defines the `IsCompleted` property. While the called thread is executing, the caller can include code it can execute in a **`while`** loop that depends on `IsCompleted`. For example, we could have the following:

```
IAsyncResult result = myThread.BeginInvoke(10, null, null);
while(!result.IsCompleted) {
  // Do some computation
}
```

This is an effective way to accomplish something in the calling thread while waiting for the called thread to complete its work. However, if the amount of computation in the **while** loop is relatively small, this is an inefficient way to use that time (because of the time required to test `IsCompleted`). An alternative is to give the called thread a delegate with the address of a callback method and have it call that method when it is finished. The delegate is sent as the second last parameter to `BeginInvoke`. For example, consider the following call to `BeginInvoke`:

```
IAsyncResult result = myThread.BeginInvoke(10,
                    new AsyncCallback(MyMethodComplete), null);
```

The callback method is defined in the caller. Such methods often simply set a Boolean variable, for example named `isDone`, to **true**. No matter how long the called thread takes, the callback method is called only once.

13.8.2 Synchronizing Threads

There are three different ways that C# threads can be synchronized: the `Interlocked` class, the `Monitor` class from the `System.Threading` namespace, and the `lock` statement. Each of these mechanisms is designed for a specific need. The `Interlocked` class is used when the only operations that need to be synchronized are the incrementing and decrementing of an integer. These operations are done atomically with the two methods of `Interlocked`, `Increment` and `Decrement`, both of which take a reference to an integer as the parameter. For example, to increment a shared integer named `counter` in a thread, we could use

```
Interlocked.Increment(ref  counter);
```

The `lock` statement is used to mark a critical section of code in a thread. The syntax of this is as follows:

```
lock(token) {
   // The critical section
}
```

If the code to be synchronized is in a private instance method, the token is the current object, so **`this`** is used as the token for `lock`. If the code to be synchronized is in a public instance method, a new instance of **`object`** is created (in the class of the method with the code to be synchronized) and a reference to it is used as the token for `lock`.

The `Monitor` class defines five methods, `Enter`, `Wait`, `Pulse`, `PulseAll`, and `Exit`, which can be used to provide more control of the synchronization of threads. The `Enter` method, which takes an object reference as its parameter, marks the beginning of synchronization of the thread on that object. The `Wait` method suspends execution of the thread and instructs the Common Language Runtime (CLR) of .NET that this thread wants to resume its execution the next time there is an opportunity. The `Pulse` method, which also takes an object reference as its parameter, notifies one waiting thread that it now has a chance to run again. `PulseAll` is similar to Java's `notifyAll`. Threads that have been waiting are run in the order in which they called the `Wait` method. The `Exit` method ends the critical section of the thread.

The `lock` statement is compiled into a monitor, so `lock` is shorthand for a monitor. A monitor is used when the additional control (for example, with `Wait` and `PulseAll`) is needed.

.NET 4.0 added a collection of generic concurrent data structures, including structures for queues, stacks, and bags.[8] These new classes are thread safe, meaning that they can be used in a multithreaded program without requiring the programmer to worry about competition synchronization. The `System.Collections.Concurrent` namespace defines these classes, whose names are `ConcurrentQueue<T>`, `ConcurrentStack<T>`, and `ConcurrentBag<T>`. So, our producer-consumer queue program could be written in C# using a `ConcurrentQueue<T>` for the data structure and there would be no need to program the competition synchronization for it. Because these concurrent collections are defined in .NET, they are also available in all of the other .NET languages.

8. Bags are unordered collections of objects.

13.8.3 Evaluation

C#'s threads are a slight improvement over those of its predecessor, Java. For one thing, any method can be run in its own thread. Recall that in Java, only methods named `run` can run in their own threads. Java supports actor threads only, but C# supports both actor and server threads. Thread termination is also cleaner with C# (calling a method (`Abort`) is more elegant than setting the thread's pointer to **`null`**). Synchronization of thread execution is more sophisticated in C#, because C# has several different mechanisms, each for a specific application. Java's `Lock` variables are similar to the locks of C#, except that in Java, a lock must be explicitly unlocked with a call to `unlock`. This provides one more way to create erroneous code. C# threads, like those of Java, are lightweight, so although they are more efficient, they cannot be as versatile as Ada's tasks. The availability of the concurrent collection classes is another advantage C# has over the other nonfunctional languages discussed in this chapter.

13.9 Concurrency in Functional Languages

This section provides a brief overview of support for concurrency in several functional programming languages.

13.9.1 Multi-LISP

Multi-LISP (Halstead, 1985) is an extension to Scheme that allows the programmer to specify program parts that can be executed concurrently. These forms of concurrency are implicit; the programmer is simply telling the compiler (or interpreter) some parts of the program that can be run concurrently.

One of the ways a programmer can tell the system about possible concurrency is the `pcall` construct. If a function call is embedded in a `pcall` construct, the parameters to the function can be evaluated concurrently. For example, consider the following `pcall` construct:

```
(pcall f a b c d)
```

The function is `f`, with parameters `a`, `b`, `c`, and `d`. The effect of `pcall` is that the parameters of the function can be evaluated concurrently (any or all of the parameters could be complicated expressions). Unfortunately, whether this process can be safely used, that is, without affecting the semantics of the function evaluation, is the responsibility of the programmer. This is actually a simple matter if the language does not allow side effects or if the programmer designed the function not to have side effects or at least to have limited ones. However, Multi-LISP does allow some side effects. If the function was not written to avoid side effects, it may be difficult for the programmer to determine whether `pcall` can be safely used.

The `future` construct of Multi-LISP is a more interesting and potentially

more productive source of concurrency. As with `pcall`, a function call is wrapped in a `future` construct. Such a function is evaluated in a separate thread, with the parent thread continuing its execution. The parent thread continues until it needs to use the return value of the function. If the function has not completed its execution when its result is needed, the parent thread waits until it has before it continues.

If a function has two or more parameters, they can also be wrapped in `future` constructs, in which case their evaluations can be done concurrently in separate threads.

These are the only additions to Scheme in Multi-LISP.

13.9.2 Concurrent ML

Concurrent ML (CML) is an extension to ML that includes a form of threads and a form of synchronous message passing to support concurrency. The language is completely described in Reppy (1999).

A thread is created in CML with the `spawn` primitive, which takes the function as its parameter. In many cases, the function is specified as an anonymous function. As soon as the thread is created, the function begins its execution in the new thread. The return value of the function is discarded. The effects of the function are either output produced or through communications with other threads. Either the parent thread (the one that spawned the new thread) or the child thread (the new one) could terminate first and it would not affect the execution of the other.

Channels provide the means of communicating between threads. A channel is created with the `channel` constructor. For example, the following statement creates a channel of arbitrary type named `mychannel`:

```
let val mychannel = channel()
```

The two primary operations (functions) on channels are for sending (`send`) and receiving (`recv`) messages. The type of the message is inferred from the send operation. For example, the following function call sends the integer

value `7`, and therefore the type of the channel is then inferred to be integer:

```
send(mychannel, 7)
```

The `recv` function names the channel as its parameter. Its return value is the value it received.

Because CML communications are synchronous, a message is both sent and received only if both the sender and the receiver are ready. If a thread sends a message on a channel and no other thread is ready to receive on that channel, the sender is blocked and waits for another thread to execute a `recv` on the channel. Likewise, if a `recv` is executed on a channel by a thread but no other thread has sent a message on that channel, the thread that ran the `recv` is blocked and waits for a message on that channel.

Because channels are types, functions can take them as parameters.

As was the case with Ada's synchronous message passing, an issue with CML synchronous message passing is deciding which message to choose when more than one channel has received one. And the same solution is used: the guarded command **`do-od`** construct that chooses randomly among messages to different channels.

The synchronization mechanism of CML is the *event*. An explanation of this complicated mechanism is beyond the scope of this chapter (and this book).

13.9.3 F#

Part of the F# support for concurrency is based on the same .NET classes that are used by C#, specifically `System.Threading.Thread`. For example, suppose we want to run the function `myConMethod` in its own thread. The following function, when called, will create the thread and start the execution of the function in the new thread:

```
let createThread() =
    let newThread = new Thread(myConMethod)
    newThread.Start()
```

Recall that in C#, it is necessary to create an instance of a predefined delegate, `ThreadStart`, send its constructor the name of the subprogram, and send the new delegate instance as a parameter to the `Thread` constructor. In F#, if a function expects a delegate as its parameter, a lambda expression or a function can be sent and the compiler will behave as if you sent the delegate. So, in the above code, the function `myConMethod` is sent as the parameter to the `Thread` constructor, but what is actually sent is a new instance of `ThreadStart` (to which was sent `myConMethod`).

The `Thread` class defines the `Sleep` method, which puts the thread from which it is called to sleep for the number of milliseconds that is sent to it as a parameter.

Shared immutable data does not require synchronization among the threads that access it. However, if the shared data is mutable, which is possible in F#, locking will be required to prevent corruption of the shared data by multiple threads attempting to change it. A mutable variable can be locked while a function operates on it to provide synchronized access to the object with the `lock` function. This function takes two parameters, the first of which is the variable to be changed. The second parameter is a lambda expression that changes the variable.

A mutable heap-allocated variable is of type `ref`. For example, the following declaration creates such a variable named `sum` with the initial value of `0`:

```
let sum = ref 0
```

A `ref` type variable can be changed in a lambda expression that uses the ALGOL/Pascal/Ada assignment operator, `:=`. The `ref` variable must be prefixed with an exclamation point (`!`) to get its value. In the following, the mutable variable `sum` is locked while the lambda expression adds the value of `x` to it:

```
lock(sum) (fun () -> sum := !sum + x)
```

Threads can be called asynchronously, just as with C#, using the same subprograms, `BeginInvoke` and `EndInvoke`, as well as the `IAsyncResult` interface to facilitate the determination of the completion of the execution of

the asynchronously called thread.

As stated previously, F# has the concurrent generic collections of .NET available to its programs. This can save a great deal of programming effort when building multithreaded programs that need a shared data structure in the form of a queue, stack, or bag.

13.10 Statement-Level Concurrency

In this section, we take a brief look at language design for statement-level concurrency. From the language design point of view, the objective of such designs is to provide a mechanism that the programmer can use to inform the compiler of ways it can map the program onto a multiprocessor architecture.9

9. Although ALGOL 68 included a semaphore type that was meant to deal with statement-level concurrency, we do not discuss that application of semaphores here.

In this section, only one collection of linguistic constructs from one language for statement-level concurrency is discussed: High-Performance Fortran.

13.10.1 High-Performance Fortran

High-Performance Fortran (HPF; ACM, 1993b) is a collection of extensions to Fortran 90 that are meant to allow programmers to specify information to the compiler to help it optimize the execution of programs on multiprocessor computers. HPF includes both new specification statements and intrinsic, or built-in, subprograms. This section discusses only some of the HPF statements.

The primary specification statements of HPF are for specifying the number of processors, the distribution of data over the memories of those processors, and the alignment of data with other data in terms of memory placement. The HPF specification statements appear as special comments in a Fortran program. Each of them is introduced by the prefix `!HPF$`, where `!` is the character used to begin lines of comments in Fortran 90. This prefix makes them invisible to Fortran 90 compilers but easy for HPF compilers to recognize.

The PROCESSORS specification has the following form:

```
!HPF$ PROCESSORS procs (n)
```

This statement is used to specify to the compiler the number of processors that can be used by the code generated for this program. This information is used in conjunction with other specifications to tell the compiler how data are to be distributed to the memories associated with the processors.

The DISTRIBUTE and ALIGN specifications are used to provide information to the compiler on machines that do not share memory—that is, each processor has its own memory. The assumption is that an access by a processor to its own memory is faster than an access to the memory of another processor.

The DISTRIBUTE statement specifies what data are to be distributed and the kind of distribution that is to be used. Its form is as follows:

```
!HPF$ DISTRIBUTE (kind) ONTO procs :: identifier_list
```

In this statement, kind can be either BLOCK or CYCLIC. The identifier list is the names of the array variables that are to be distributed. A variable that is specified to be BLOCK distributed is divided into *n* equal groups, where each group consists of contiguous collections of array elements evenly distributed over the memories of all the processors. For example, if an array with 500 elements named LIST is BLOCK distributed over 5 processors, the first 100 elements of LIST will be stored in the memory of the first processor, the second 100 in the memory of the second processor, and so forth. A CYCLIC distribution specifies that individual elements of the array are cyclically stored in the memories of the processors. For example, if LIST is CYCLIC distributed, again over five processors, the first element of LIST will be stored in the memory of the first processor, the second element in the memory of the second processor, and so forth.

The form of the ALIGN statement is

```
ALIGN array1_element WITH array2_element
```

ALIGN is used to relate the distribution of one array with that of another. For example,

```
ALIGN list1(index) WITH list2(index+1)
```

specifies that the `index` element of `list1` is to be stored in the memory of the same processor as the `index+1` element of `list2`, for all values of `index`. The two array references in an `ALIGN` appear together in some statement of the program. Putting them in the same memory (which means the same processor) ensures that the references to them will be as close as possible.

Consider the following example code segment:

```
     REAL list_1 (1000), list_2 (1000)
     INTEGER list_3 (500), list_4 (501)
!HPF$ PROCESSORS proc (10)
!HPF$ DISTRIBUTE (BLOCK) ONTO procs :: list_1, list_2
!HPF$ ALIGN list_3 (index) WITH list_4 (index+1)
     . . .
     list_1 (index) = list_2 (index)
     list_3 (index) = list_4 (index+1)
```

In each execution of these assignment statements, the two referenced array elements will be stored in the memory of the same processor.

The HPF specification statements provide information for the compiler that it may or may not use to optimize the code it produces. What the compiler actually does depends on its level of sophistication and the particular architecture of the target machine.

The `FORALL` statement specifies a sequence of assignment statements that may be executed concurrently. For example,

```
FORALL (index = 1:1000)
  list_1(index) = list_2(index)
END FORALL
```

specifies the assignment of the elements of `list_2` to the corresponding elements of `list_1`. However, the assignments are restricted to the following order: the right side of all 1,000 assignments must be evaluated first, before any assignments take place. This permits concurrent execution of all of the assignment statements. In addition to assignment statements, `FORALL` statements can appear in the body of a `FORALL` construct. The `FORALL` statement is a good match with vector machines, in which the same

instruction is applied to many data values, usually in one or more arrays. The HPF `FORALL` statement is included in Fortran 95 and subsequent versions of Fortran.

We have briefly discussed only a small part of the capabilities of HPF. However, it should be enough to provide the reader with an idea of the kinds of language extensions that are useful for programming computers with possibly large numbers of processors.

C# 4.0 (and the other .NET languages) include two methods that behave somewhat like `FORALL`. They are loop control statements in which the iterations can be unrolled and the bodies executed concurrently. These are `Parallel.For` and `Parallel.ForEach`.

SUMMARY

Concurrent execution can be at the instruction, statement, or subprogram level. We use the phrase *physical concurrency* when multiple processors are actually used to execute concurrent units. If concurrent units are executed on a single processor, we use the term *logical concurrency*. The underlying conceptual model of all concurrency can be referred to as *logical concurrency*.

Most multiprocessor computers fall into one of two broad categories—SIMD or MIMD. MIMD computers can be distributed.

Languages that support subprogram-level concurrency must provide two fundamental capabilities: mutually exclusive access to shared data structures (competition synchronization) and cooperation among tasks (cooperation synchronization).

Tasks can be in any one of five different states: new, ready, running, blocked, or dead.

Rather than designing language constructs for supporting concurrency, sometimes libraries, such as OpenMP, are used.

The design issues for language support for concurrency are how competition and cooperation synchronization are provided, how an application can influence task scheduling, how and when tasks start and end their executions, and how and when they are created.

A semaphore is a data structure consisting of an integer and a task description queue. Semaphores can be used to provide both competition and cooperation synchronization among concurrent tasks. It is easy to use semaphores incorrectly, resulting in errors that cannot be detected by the compiler, linker, or run-time system.

Monitors are data abstractions that provide a natural way of providing mutually exclusive access to data shared among tasks. They are supported by

several programming languages, among them Ada, Java, and C#. Cooperation synchronization in languages with monitors must be provided with some form of semaphores.

The underlying concept of the message-passing model of concurrency is that tasks send each other messages to synchronize their execution.

Ada provides complex but effective constructs, based on the message-passing model, for concurrency. Ada's tasks are heavyweight tasks. Tasks communicate with each other through the rendezvous mechanism, which is synchronous message passing. A rendezvous is the action of a task accepting a message sent by another task. Ada includes both simple and complicated methods of controlling the occurrences of rendezvous among tasks.

Ada 95+ includes additional capabilities for the support of concurrency, primarily protected objects. Ada 95+ supports monitors in two ways, with tasks and with protected objects.

Java supports lightweight concurrent units in a relatively simple but effective way. Any class that either inherits from `Thread` or implements `Runnable` can override a method named `run` and have that method's code executed concurrently with other such methods and with the main program. Competition synchronization is specified by defining methods that access shared data to be implicitly synchronized. Small sections of code can also be implicitly synchronized. A class whose methods are all synchronized is a monitor. Cooperation synchronization is implemented with the methods `wait`, `notify`, and `notifyAll`. The `Thread` class also provides the `sleep`, `yield`, `join`, and `interrupt` methods.

Java has direct support for counting semaphores through its `Semaphore` class and its `acquire` and `release` methods. It also had some classes for providing nonblocking atomic operations, such as addition, increment, and decrement operations for integers. Java also provides explicit locks with the `Lock` interface and `ReentrantLock` class and its `lock` and `unlock` methods. In addition to implicit synchronization using **`synchronized`**, Java provides implicit nonblocking synchronization of **`int`**, **`long`**, and **`boolean`** type variables, as well as references and arrays. In these cases, atomic getters, setters, add, increment, and decrement operations are provided.

C#’s support for concurrency is based on that of Java but is slightly more sophisticated. Any method can be run in a thread. Both actor and server threads are supported. All threads are controlled through associated delegates. Server threads can be synchronously called with `Invoke` or asynchronously called with `BeginInvoke`. A callback method address can be sent to the called thread. Three kinds of thread synchronization are supported with the `Interlocked` class, which provides atomic increment and decrement operations, the `Monitor` class, and the `lock` statement.

All .NET languages have the use of the generic concurrent data structures for stacks, queues, and bags, for which competition synchronization is implicit.

Multi-LISP extends Scheme slightly to allow the programmer to inform the implementation about program parts that can be executed concurrently. Concurrent ML extends ML to support a form of threads and a form of synchronous message passing among those threads. This message passing is designed with channels. F# programs have access to all of the .NET support classes for concurrency. Data shared among threads that is mutable can have access synchronized.

High-Performance Fortran includes statements for specifying how data is to be distributed over the memory units connected to multiple processors. Also included are statements for specifying collections of statements that can be executed concurrently.

BIBLIOGRAPHIC NOTES

- The general subject of concurrency is discussed at great length in Andrews and Schneider (1983), Holt et al. (1978), and Ben-Ari (1982).

- The monitor concept is developed and its implementation in Concurrent Pascal is described by Brinch Hansen (1977).

- The early development of the message-passing model of concurrent unit control is discussed by Hoare (1978) and Brinch Hansen (1978). An in-depth discussion of the development of the Ada tasking model can be found in Ichbiah et al. (1979). Ada 95 is described in detail in ARM (1995). High-Performance Fortran is described in ACM (1993b).

REVIEW QUESTIONS

1. What are the three possible levels of concurrency in programs?
2. Describe the logical architecture of an SIMD computer.
3. Describe the logical architecture of an MIMD computer.
4. What level of program concurrency is best supported by SIMD computers?
5. What level of program concurrency is best supported by MIMD computers?
6. Describe the logical architecture of a vector processor.
7. What is the difference between physical and logical concurrency?
8. What is a thread of control in a program?
9. Why are coroutines called quasi-concurrent?
10. What is a multithreaded program?
11. What are four reasons for studying language support for concurrency?
12. What is a heavyweight task? What is a lightweight task?
13. Define *task*, *synchronization*, *competition* and *cooperation synchronization*, *liveness*, *race condition*, and *deadlock*.
14. What kind of tasks do not require any kind of synchronization?
15. Describe the five different states in which a task can be.
16. What is a task descriptor?

17. In the context of language support for concurrency, what is a guard?

18. What is the purpose of a task-ready queue?

19. What are the two primary design issues for language support for concurrency?

20. Describe the actions of the wait and release operations for semaphores.

21. What is a binary semaphore? What is a counting semaphore?

22. What are the primary problems with using semaphores to provide synchronization?

23. What advantage do monitors have over semaphores?

24. In what three common languages can monitors be implemented?

25. Define *rendezvous*, **`accept`** *clause*, **`entry`** *clause*, *actor task*, *server task*, *extended* **`accept`** *clause*, *open* **`accept`** *clause*, *closed* **`accept`** *clause*, and *completed task*.

26. Which is more general, concurrency through monitors or concurrency through message passing?

27. Are Ada tasks created statically or dynamically?

28. What purpose does an extended **`accept`** clause serve?

29. How is cooperation synchronization provided for Ada tasks?

30. What is the advantage of protected objects in Ada 95 over tasks for providing access to shared data objects?

31. Specifically, what Java program unit can run concurrently with the main method in an application program?

32. Are Java threads lightweight or heavyweight tasks?

33. What does the Java `sleep` method do?

34. What does the Java `yield` method do?

35. What does the Java `join` method do?

36. What does the Java `interrupt` method do?

37. What are the two Java constructs that can be declared to be `synchronized`?

38. How can the priority of a thread be set in Java?

39. Can Java threads be actor threads, server threads, or either?

40. Describe the actions of the three Java methods that are used to support cooperation synchronization.

41. What kind of Java object is a monitor?

42. Explain why Java includes the `Runnable` interface.

43. What are the two methods used with Java `Semaphore` objects?

44. What is the advantage of the nonblocking synchronization in Java?

45. What are the methods of the Java `AtomicInteger` class and what is the purpose of this class?

46. How are explicit locks supported in Java?

47. What kinds of methods can be run in a C# thread?

48. Can C# threads be actor threads, server threads, or either?

49. What are the two ways a C# thread can be called synchronously?

50. How can a C# thread be called asynchronously?

51. How is the returned value from an asynchronously called thread retrieved in C#?

52. What is different about C#'s `Sleep` method, relative to Java's `sleep`?

53. What exactly does C#'s `Abort` method do?

54. What is the purpose of C#'s `Interlocked` class?

55. What does the C# `lock` statement do?

56. On what language is Multi-LISP based?

57. What is the semantics of Multi-LISP's `pcall` construct?

58. How is a thread created in CML?

59. What is the type of an F# heap-allocated mutable variable?

60. Why don't F# immutable variables require synchronized access in a multithreaded program?

61. What is the objective of the specification statements of HPF?

62. What is the purpose of the `FORALL` statement of HPF and Fortran?

PROBLEM SET

1. Explain clearly why competition synchronization is not a problem in a programming environment that supports coroutines but not concurrency.

2. What is the best action a system can take when deadlock is detected?

3. Busy waiting is a method whereby a task waits for a given event by continuously checking for that event to occur. What is the main problem with this approach?

4. In the producer-consumer example of Section 13.3, suppose that we incorrectly replaced the `release(access)` in the consumer process with `wait(access)`. What would be the result of this error on execution of the system?

5. From a book on assembly language programming for a computer that uses an Intel Pentium processor, determine what instructions are provided to support the construction of semaphores.

6. Suppose two tasks, `A` and `B`, must use the shared variable `Buf_Size`. Task `A` adds 2 to `Buf_Size`, and task `B` subtracts 1 from it. Assume that such arithmetic operations are done by the three-step process of fetching the current value, performing the arithmetic, and putting the new value back. In the absence of competition synchronization, what sequences of events are possible and what values result from these operations? Assume that the initial value of `Buf_Size` is 6.

7. Compare the Java competition synchronization mechanism with that of Ada.

8. Compare the Java cooperation synchronization mechanism with that of Ada.

9. What happens if a monitor procedure calls another procedure in the same monitor?

10. Explain the relative safety of cooperation synchronization using semaphores and using Ada's **when** clauses in tasks.

PROGRAMMING EXERCISES

1. Write an Ada task to implement general semaphores.

2. Write an Ada task to manage a shared buffer such as the one in our example, but use the semaphore task from Programming Exercise 1.

3. Define semaphores in Ada and use them to provide both cooperation and competition synchronization in the shared-buffer example.

4. Write Programming Exercise 3 using Java.

5. Write the shared-buffer example of the chapter in C#.

6. The reader-writer problem can be stated as follows: A shared memory location can be concurrently read by any number of tasks, but when a task must write to the shared memory location, it must have exclusive access. Write a Java program for the reader-writer problem.

7. Write Programming Exercise 6 using Ada.

8. Write Programming Exercise 6 using C#.

14 Exception Handling and Event Handling

This chapter discusses programming language support for two related parts of many contemporary programs: exception handling and event handling. Both exceptions and events occur at times that cannot be predetermined, and both are best handled with special language constructs and processes. Some of these constructs and processes—for example, propagation—are similar for exception handling and event handling.

We first describe the fundamental concepts of exception handling, including hardware- and software-detectable exceptions, exception handlers, and the raising of exceptions. Then, the design issues for exception handling are introduced and discussed, including the binding of exceptions to exception handlers, continuation, and default handlers. This section is followed by descriptions and evaluations of the exception-handling facilities of two programming languages: C++ and Java. Brief introductions to exception handling in Python and Ruby are then presented.

The latter part of this chapter is about event handling. We first present an - introduction to the basic concepts of event handling. This is followed by

discussions of the event-handling approaches of Java and C#.

14.1 Introduction to Exception Handling

Most computer hardware systems are capable of detecting certain run-time error conditions, such as floating-point overflow. Early programming - languages were designed and implemented in such a way that the user program could neither detect nor attempt to deal with such errors. In these languages, the occurrence of such an error simply causes the program to be terminated and control to be transferred to the operating system. The typical operating system reaction to a run-time error is to display a diagnostic message, which may be meaningful and therefore useful, or highly cryptic. After displaying the message, the program is terminated.

In the case of input and output operations, however, the situation is somewhat different. For example, a Fortran `Read` statement can intercept input errors and end-of-file conditions, both of which are detected by the input device hardware. In both cases, the `Read` statement can specify the label of some statement in the user program that deals with the condition. In the case of the end-of-file, the condition obviously is not always considered an error. In most cases, it is nothing more than a signal that one kind of processing is completed and another kind must begin. In spite of the obvious difference between end-of-file and events that are always errors, such as a failed input process, Fortran handles both situations with the same mechanism. Consider the following Fortran `Read` statement:

```
Read(Unit=5, Fmt=1000, Err=100, End=999) Weight
```

The `Err` clause specifies that control is to be transferred to the statement labeled `100` if an error occurs in the read operation. The `End` clause specifies that control is to be transferred to the statement labeled `999` if the read operation encounters the end of the file. So, Fortran uses simple branches for both input errors and end-of-file.

There is a category of serious errors that are not detectable by hardware but

can be detected by code generated by the compiler. For example, array subscript range errors are almost never detected by hardware,[1] but they lead to serious errors that often are not noticed until later in the program execution.

1. In the 1970s, there were some computers that *did* detect subscript range errors in hardware.

Detection of subscript range errors is sometimes required by the language design. For example, the Java language specification requires Java compilers to generate code to check the correctness of every subscript expression (they do not generate such code when it can be determined at compile time that a subscript expression cannot have an out-of-range value, for example, if the subscript is a literal). In C, subscript ranges are not checked because the cost of such checking was (and still is) not believed to be worth the benefit of detecting such errors. In some compilers for some languages, subscript range checking can be selected (if not turned on by default) or turned off (if it is on by default) as desired in the program or in the command that executes the compiler.

The designers of most contemporary languages have included mechanisms that allow programs to react in a standard way to certain run-time errors, as well as other program-detected unusual events. Programs may also be notified when certain events are detected by hardware or system software, so that they also can react to these events.

14.1.1 Basic Concepts

We consider both the errors detected by hardware, such as disk read errors, and unusual conditions, such as end-of-file (which is also detected by hardware), to be exceptions. We further extend the concept of an exception to include errors or unusual conditions that are software-detectable (by either a software interpreter or the user code itself). Accordingly, we define **exception** to be any unusual event, erroneous or not, that is detectable by either hardware or software and that may require special processing.

The special processing that may be required when an exception is detected is called **exception handling**. This processing is done by a code unit or segment called an **exception handler**. An exception is **raised** when its associated event occurs. In some C-based languages, exceptions are said to be *thrown*, rather than *raised*.2 Different kinds of exceptions require different exception handlers. Detection of end-of-file nearly always requires some specific program action. But, clearly, that action would not also be appropriate for an array index range error exception. In some cases, the only action is the generation of an error message and an orderly termination of the program.

2. C++ was the first C-based language that included exception handling. The word *throw* was used, rather than *raise*, because the standard C library includes a function named `raise`.

The absence of separate or specific exception-handling facilities in a language does not preclude the handling of user-defined, software-detected exceptions. Such an exception detected within a program unit is often handled by the unit's caller. One possible design is to send an auxiliary parameter, which is used as a status variable. The status variable is assigned a value in the called subprogram according to the correctness and/or normalness of the results of its computations. Immediately upon return from the called unit, the caller tests the status variable. If the value indicates that an exception has occurred, the handler, which may reside in the calling unit, can be enacted. Many of the C standard library functions use a variant of this approach: The return values are used as error indicators.

Another possibility is to pass a label parameter to the subprogram. Of course, this approach is possible only in languages that allow labels to be used as parameters. Passing a label allows the called unit to return to a different point in the caller if an exception has occurred. As in the first alternative, the handler is often a segment of the calling unit's code. This is a common use of label parameters in Fortran.

A third possibility is to have the handler defined as a separate subprogram whose name is passed as a parameter to the called unit. In this case, the handler subprogram is provided by the caller, but the called unit calls the handler when an exception is raised. One problem with this approach is that one is required to send a handler subprogram with *every* call to *every*

subprogram that takes a handler subprogram as a parameter, whether it is needed or not. Furthermore, to deal with several different kinds of exceptions, several different handler routines would need to be passed, complicating the code.

If it is desirable to handle an exception in the unit in which it is detected, the handler is included as a segment of code in that unit.

There are some definite advantages to having exception handling built into a language. First, without exception handling, the code required to detect error conditions can considerably clutter a program. For example, suppose a subprogram includes expressions that contain 10 references to elements of a matrix named `mat`, and any one of them could have an index out-of-range error. Further suppose that the language does not require index range checking. Without built-in index range checking, every one of these operations may need to be preceded by code to detect a possible index range error. For example, consider the following reference to an element of `mat`, which has 10 rows and 20 columns:

```
if (row >= 0 && row < 10 && col >= 0 && col < 20)
  sum += mat[row][col];
else
  System.out.println("Index range error on mat, row = " +
                     row + " col = " + col);
```

The presence of exception handling in the language would permit the -compiler to insert machine code for such checks before every array element access, greatly shortening and simplifying the source program.

Another advantage of language support for exception handling results from exception propagation. Exception propagation allows an exception raised in one program unit to be handled in some other unit in its dynamic or static ancestry. This allows a single exception handler to be used for any number of different program units. This reuse can result in significant savings in development cost, program size, and program complexity.

A language that supports exception handling encourages its users to consider all of the events that could occur during program execution and how they can be handled. This approach is far better than not considering such possibilities

and simply hoping nothing will go wrong.

Finally, there are programs in which dealing with nonerroneous but unusual situations can be simplified with exception handling, and in which program structure can become overly convoluted without it.

14.1.2 Design Issues

We now explore some of the design issues for an exception-handling system when it is part of a programming language. Such a system might allow both predefined and user-defined exceptions and exception handlers. Note that predefined exceptions are implicitly raised, whereas user-defined exceptions must be explicitly raised by user code. Consider the following skeletal subprogram that includes an exception-handling mechanism for an implicitly raised exception:

```
void example() {
  . . .
  average = sum / total;
  . . .
  return;
/* Exception handlers */
  when zero_divide {
    average = 0;
    printf("Error–divisor (total) is zero\n");
  }
  . . .
}
```

The exception of division by zero, which is implicitly raised, causes control to transfer to the appropriate handler, which is then executed.

The first design issue for exception handling is how an exception occurrence is bound to an exception handler. This issue occurs on two different levels. On the unit level, there is the question of how the same exception being raised at different points in a unit can be bound to different handlers within the unit. For example, in the example subprogram, there is a handler for a -division-by-zero exception that appears to be written to deal with an occurrence of division by zero in a particular statement (the one shown). But

suppose the function includes several other expressions with division operators. For those operators, this handler would probably not be appropriate. So, it should be possible to bind the exceptions that can be raised by particular statements to particular handlers, even though the same exception can be raised by many different statements.

At a higher level, the binding question arises when there is no exception handler local to the unit in which the exception is raised. In this case, the language designer must decide whether to propagate the exception to some other unit and, if so, where. How this propagation takes place and how far it goes have an important impact on the writability of exception handlers. For example, if handlers must be local, then many handlers must be written, which complicates both the writing and reading of the program. On the other hand, if exceptions are propagated, a single handler might handle the same exception raised in several program units, which may require the handler to be more general than one would prefer.

An issue that is related to the binding of an exception to an exception handler is whether information about the exception is made available to the handler.

history note

PL/I (ANSI, 1976) pioneered the concept of allowing user programs to be directly involved in exception handling. The language allowed the user to write exception handlers for a long list of language-defined exceptions. Furthermore, PL/I introduced the concept of user-defined exceptions, which allow programs to create software-detected exceptions. These exceptions use the same mechanisms that are used for the built-in exceptions.

Since PL/I was designed, a substantial amount of work has been done to design alternative methods of exception handling, and exception-handling mechanisms have been included in a long list of subsequent programming languages.

After an exception handler executes, either control can transfer to somewhere in the program outside of the handler code or program execution can simply

terminate. We term this the question of control continuation after handler execution, or simply **continuation**. Termination is obviously the simplest choice, and in many error exception conditions, the best. However, in other situations, particularly those associated with unusual but not erroneous events, the choice of continuing execution is best. This design is called **resumption**. In these cases, some conventions must be chosen to determine where execution should continue. It might be the statement that raised the exception, the statement after the statement that raised the exception, or possibly some other unit. The choice to return to the statement that raised the exception may seem like a good one, but in the case of an error exception, it is useful only if the handler somehow is able to modify the values or operations that caused the exception to be raised. Otherwise, the exception will simply be reraised. The required modification for an error exception is often very difficult to predict. Even when possible, however, it may not be a sound practice. It allows the program to remove the symptom of a problem without removing the cause.

The two issues of binding of exceptions to handlers and continuation are illustrated in Figure 14.1.

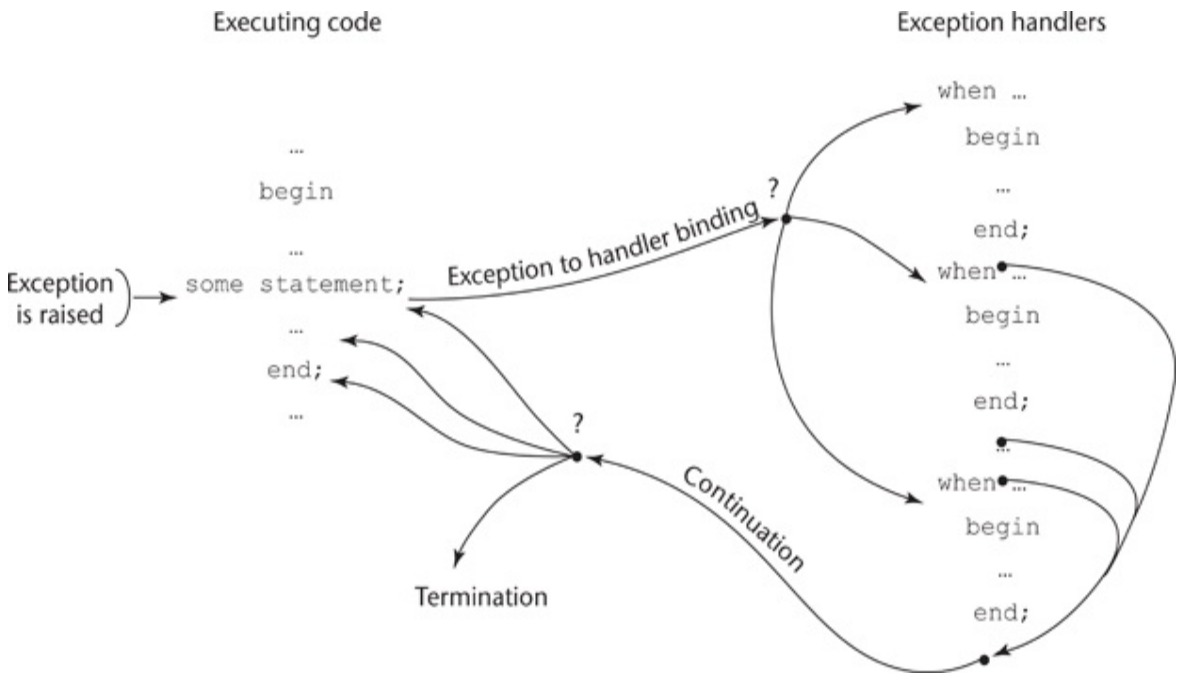

Figure 14.1 Exception-handling

control flow

Figure 14.1 Full Alternative Text

When exception handling is included, a subprogram's execution can terminate in two ways: when its execution is complete or when it encounters an exception.3 In some situations, it is necessary to complete some computation regardless of how subprogram execution terminates. The ability to specify such a computation is called *finalization*. The choice of whether to support finalization is obviously a design issue for exception handling.

3. Of course, even if the language does not support exception handling, a subprogram could terminate due to a system-detected error.

Another design issue is the following: If users are allowed to define exceptions, how are these exceptions specified? The usual answer is to require that they be declared in the specification parts of the program units in which they can be raised. The scope of a declared exception is usually the scope of the program unit that contains the declaration.

In the case where a language provides predefined exceptions, several other design issues follow. For example, should the language run-time system provide default handlers for the built-in exceptions, or should the user be required to write handlers for all exceptions? Another question is whether predefined exceptions can be raised explicitly by the user program. This usage can be convenient if there are software-detectable situations in which the user would like to use a predefined handler.

Another issue is whether hardware-detectable errors can be handled by user programs. If not, all exceptions obviously are software detectable. A related question is whether there should be any predefined exceptions. Predefined exceptions are implicitly raised by either hardware or system software.

The exception-handling design issues can be summarized as follows:

- How and where are exception handlers specified, and what is their scope?

- How is an exception occurrence bound to an exception handler?
- Can information about an exception be passed to the handler?
- Where does execution continue, if at all, after an exception handler completes its execution? (This is the question of continuation or resumption.)
- Is some form of finalization provided?
- How are user-defined exceptions specified?
- If there are predefined exceptions, should there be default exception handlers for programs that do not provide their own?
- Can predefined exceptions be explicitly raised?
- Are hardware-detectable errors treated as exceptions that may be handled?
- Are there any predefined exceptions?

We are now in a position to examine the exception-handling facilities of several contemporary programming languages.

14.2 Exception Handling in C++

The exception handling of C++ was accepted by the ANSI C++ standardization committee in 1990 and subsequently found its way into C++ implementations. The design is based in part on the exception handling of CLU, Ada, and ML.

14.2.1 Exception Handlers

C++ uses a special construct that is introduced with the reserved word **`try`** to specify the scope for exception handlers. A **`try`** construct includes a compound statement called the **try clause** and a list of exception handlers. The compound statement defines the scope of the following handlers. The general form of this construct is as follows:

```
try {
//** Code that might raise an exception
} catch (formal parameter) {
//** A handler body
}
. . .
catch(formal parameter) {
//** A handler body
}
```

Each **`catch`** function is an exception handler. A **`catch`** function can have only a single formal parameter, which is similar to a formal parameter in a function definition in C++, including the possibility of it being an ellipsis (. . .). A handler with an ellipsis formal parameter is the catch-all handler; it is enacted for any raised exception if no appropriate handler was found. The formal parameter also can be a naked type specifier, such as **`float`**, as in a function prototype. In such a case, the only purpose of the formal parameter is to make the handler uniquely identifiable. When information about the exception is to be passed to the handler, the formal parameter includes a variable name that is used for that purpose. Because the class of the

parameter can be any user-defined class, the parameter can include as many data members as are necessary. Binding exceptions to handlers are discussed in Section 14.3.2.

In C++, exception handlers can include any C++ code.

14.2.2 Binding Exceptions to Handlers

C++ exceptions are raised only by the explicit statement **`throw`**, whose general form in EBNF is as follows:

```
throw [expression];
```

The brackets here are metasymbols used to specify that the expression is optional. A **`throw`** without an operand can appear only in a handler. When it appears there, it reraises the exception, which is then handled elsewhere.

The type of the **`throw`** expression selects the particular handler, which of course must have a "matching" type formal parameter. In this case, *matching* means the following: A handler with a formal parameter of type `T`, **`const`** `T`, `T&` (a reference to an object of type `T`), or **`const`** `T&` matches a **`throw`** with an expression of type `T`. In the case where `T` is a class, a handler whose parameter is type `T` or any class that is an ancestor of `T` matches. There are more complicated situations in which a **`throw`** expression matches a formal parameter, but they are not described here.

An exception raised in a **`try`** clause causes an immediate end to the execution of the code in that **`try`** clause. The search for a matching handler begins with the handlers that immediately follow the **`try`** clause. The matching process is done sequentially on the handlers until a match is found. This means that if any other match precedes an exactly matching handler, the exactly matching handler will not be used. Therefore, handlers for specific exceptions are placed at the top of the list, followed by more generic handlers. The last handler is often one with an ellipsis (. . .) formal parameter, which matches

any exception. This would guarantee that all exceptions are caught.

If an exception is raised in a **try** clause and there is no matching handler associated with that **try** clause, the exception is propagated. If the **try** clause is nested inside another **try** clause, the exception is propagated to the handlers associated with the outer **try** clause. If none of the enclosing **try** clauses yields a matching handler, the exception is propagated to the caller of the function in which it was raised. If the call to the function was not in a **try** clause, the exception is propagated to that function's caller. If no matching handler is found in the program through this propagation process, the default handler is called. This handler is further discussed in Section 14.2.4.

14.2.3 Continuation

After a handler has completed its execution, control flows to the first statement following the **try** construct (the statement immediately after the last handler in the sequence of handlers of which it is an element). A handler may reraise an exception, using a **throw** without an expression, in which case that exception is propagated.

14.2.4 Other Design Choices

In terms of the design issues summarized in Section 14.1.2, the exception handling of C++ is simple. There are *only* user-defined exceptions, and they are not specified (though they might be declared as new classes). There is a default exception handler, `unexpected`, whose only action is to terminate the program. This handler catches all exceptions not caught by the program. It can be replaced by a user-defined handler. The replacement handler must be a function that returns **void** and takes no parameters. The replacement function is set by assigning its name to `set_terminate`.

A C++ function can list the types of the exceptions (the types of the **throw** expressions) that it could raise. This is done by attaching the reserved word **throw**, followed by a parenthesized list of these types, to the function header.

For example,

```
int fun() throw (int, char *) { . . . }
```

specifies that the function `fun` could raise exceptions of type **`int`** and **`char *`** but no others. The purpose of the **`throw`** clause is to notify users of the function what exceptions might be raised by the function. The **`throw`** clause is in effect a contract between the function and its callers. It guarantees that no other exception will be raised in the function.

If the types in the **`throw`** clause are classes, then the function can raise any exception that is derived from the listed classes. If a function header has a **`throw`** clause and raises an exception that is not listed in the **`throw`** clause and is not derived from a class listed there, the default handler is called. Note that this error cannot be detected at compile time. The list of types in the list may be empty, meaning that the function will not raise any exceptions. If there is no **`throw`** specification on the header, the function can raise any exception. The list is not part of the function's type.

If a function overrides a function that has a **`throw`** clause, the overriding function cannot have a **`throw`** clause with more exceptions than the overridden function.

Although C++ has no predefined exceptions, the standard libraries define and throw exceptions, such as `out_of_range`, which can be thrown by library container classes, and `overflow_error`, which can be thrown by math library functions.

14.2.5 An Example

The following example program illustrates some simple uses of exception handlers in C++. The program computes and prints a distribution of input grades by using an array of counters. The input is a sequence of grades, terminated by a negative number. The negative number raises a `NegativeInputException` exception because the grades must be nonnegative integers. There are 10 categories of grades (0−9, 10−19, … , 90−100). The grades themselves

are used to compute indexes into an array of counters, one for each grade category. Invalid input grades are detected by trapping indexing errors in the counter array. A grade of 100 is special in the computation of the grade distribution because the categories all have 10 possible grade values, except the highest, which has 11 (90, 91, . . . , 100). (The fact that there are more possible A grades than B's or C's is conclusive evidence of the generosity of teachers.) The grade of 100 is also handled in the same exception handler that is used for invalid input data.

```
// Grade Distribution
//  Input: A list of integer values that represent
//         grades, followed by a negative number
// Output: A distribution of grades, as a percentage for
//         each of the categories 0-9, 10-19, . . .,
//         90-100.
#include <iostream>
int main() { //* Any exception can be raised
  int new_grade,
      index,
      limit_1,
      limit_2,
      freq[10] = {0,0,0,0,0,0,0,0,0,0};
// The exception definition to deal with the end of data
class NegativeInputException {
  public:
   NegativeInputException() {  //* Constructor
    cout << ”End of input data reached" << endl;
  }  //** end of constructor
}  //** end of NegativeInputException class
  try {
     while (true) {
       cout << ”Please input a grade" << endl;
       if ((cin >> new_grade) < 0)  //* End of data
         throw  NegativeInputException();
      index = new_grade / 10;
      {try {
        if (index > 9)
          throw  new_grade;
        freq[index]++;
        }  //* end of inner try compound
      catch(int  grade) {  //* Handler for index errors
        if (grade == 100)
          freq[9]++;
        else
          cout << ”Error -- new grade: " << grade
```

```
                << " is out of range" << endl;
        }  //* end of catch(int grade)
      }  //*  end of the block for the inner try-catch pair
    }  //* end of while (1)
  }  //* end of outer try block
  catch(NegativeInputException& e) {  //**Handler for
                                      //** negative input
    cout << ”Limits   Frequency" << endl;
    for (index = 0; index < 10; index++) {
      limit_1 = 10 * index;
      limit_2 = limit_1 + 9;
      if (index == 9)
        limit_2 = 100;
      cout << limit_1 << limit_2 << freq[index] << endl;
    }  //* end of for (index = 0)
  }  //* end of catch (NegativeInputException& e)
}  //* end of main
```

This program is meant to illustrate the mechanics of C++ exception handling. Note that the index range exception is often handled in C++ by overloading the indexing operation, which could then raise the exception, rather than the direct detection of the indexing operation with the selection construct used in our example.

14.2.6 Evaluation

One deficiency of exception handling in C++ is that there are no predefined hardware-detectable exceptions that can be handled by the user. Exceptions are connected to handlers through a parameter type in which the formal parameter may be omitted. The type of the formal parameter of a handler determines the condition under which it is called but may have nothing whatsoever to do with the nature of the raised exception. Therefore, the use of predefined types for exceptions certainly does not promote readability. It is much better to define classes for exceptions with meaningful names in a meaningful hierarchy that can be used for defining exceptions. The exception parameter provides a way to pass information about an exception to the exception handler.

14.3 Exception Handling in Java

In Chapter 13, the Java example program includes the use of exception - handling with little explanation. This section describes the details of Java's exception-handling capabilities.

Java's exception handling is based on that of C++, but it is designed to be more in line with the object-oriented language paradigm. Furthermore, Java includes a collection of predefined exceptions that are implicitly raised by the Java run-time system.

14.3.1 Classes of Exceptions

All Java exceptions are objects of classes that are descendants of the `Throwable` class. The Java system includes two predefined exception classes that are subclasses of `Throwable`: `Error` and `Exception`. The `Error` class and its descendants are related to errors that are thrown by the Java run-time system, such as running out of heap memory. These exceptions are never thrown by user programs, and they should never be handled there. There are two system-defined direct descendants of `Exception`: `RuntimeException` and `IOException`. As its name indicates, `IOException` is thrown when an error has occurred in an input or output operation, all of which are defined as methods in the various classes defined in the package `java.io`.

There are predefined classes that are descendants of `RuntimeException`. In most cases, `RuntimeException` is thrown when a user program causes an error. For example, `ArrayIndexOutOfBoundsException`, which is defined in `java.util`, is a commonly thrown exception that descends from `RuntimeException`. Another commonly thrown exception that descends from `RuntimeException` is `NullPointerException`.

User programs can define their own exception classes. The convention in Java is that user-defined exceptions are subclasses of `Exception`.

14.3.2 Exception Handlers

The exception handlers of Java have the same form as those of C++, except that every **`catch`** must have a parameter and the class of the parameter must be a descendant of the predefined class `Throwable`.

The syntax of the **`try`** construct in Java is exactly as that of C++, except for the **`finally`** clause described in Section 14.3.6.

14.3.3 Binding Exceptions to Handlers

Throwing an exception is simple. An instance of the exception class is given as the operand of the **`throw`** statement. For example, suppose we define an exception named `MyException` as

```
class MyException extends Exception {
  public MyException() {}
  public MyException(String message) {
    super (message);
  }
}
```

This exception can be thrown with the following statement:

```
throw new MyException();
```

One of the two constructors we have included in our new class has no parameter and the other has a `String` object parameter that it sends to the superclass (`Exception`), which displays it. Therefore, our new exception could be thrown with

```
throw new MyException
       ("a message to specify the location of the error");
```

The binding of exceptions to handlers in Java is similar to that of C++. If an

exception is thrown in the compound statement of a **try** construct, it is bound to the first handler (**catch** function) immediately following the **try** clause whose parameter is the same class as the thrown object, or an ancestor of it. If a matching handler is found, the **throw** is bound to it and it is executed.

Exceptions can be handled and then rethrown by including a **throw** statement without an operand at the end of the handler. The newly thrown exception will not be handled in the same **try** where it was originally thrown, so looping is not a concern. This rethrowing is usually done when some local action is useful, but further handling by an enclosing **try** clause or a **try** clause in the caller is necessary. A **throw** statement in a handler could also throw some exception other than the one that transferred control to this handler.

To ensure that exceptions that can be thrown in a **try** clause are always handled in a method, a special handler can be written that matches all exceptions that are derived from `Exception` simply by defining the handler with an `Exception` type parameter, as in

```
catch (Exception genericObject) {
  . . .
}
```

Because a class name always matches itself or any ancestor class, any class derived from `Exception` matches `Exception`. Of course, such an exception handler should always be placed at the end of the list of handlers, for it will block the use of any handler that follows it in the **try** construct in which it appears. This occurs because the search for a matching handler is sequential, and the search ends when a match is found.

14.3.4 Other Design Choices

As part of its reflection facilities, the Java run-time system stores the class name of every object in the program. The method `getClass` can be used to get an object that stores the class name, which itself can be gotten with the `getName` method. So, we can retrieve the name of the class of the actual parameter from the **throw** statement that caused the handler's execution. For

the handler shown earlier, this is done with

```
genericObject.getClass().getName()
```

In addition, the message associated with the parameter object, which is created by the constructor, can be gotten with

```
genericObject.getMessage()
```

Furthermore, in the case of user-defined exceptions, the thrown object could include any number of data fields that might be useful in the handler.

The **`throws`** clause of Java has the appearance and placement (in a program) that is similar to that of the **`throw`** specification of C++. However, the semantics of **`throws`** is somewhat different from that of the C++ **`throw`** clause.

The appearance of an exception class name in the **`throws`** clause of a Java method specifies that that exception class or any of its descendant exception classes can be thrown but not handled by the method. For example, when a method specifies that it can throw `IOException`, it means it can throw an `IOException` object or an object of any of its descendant classes, such as `EOFException`, and it does not handle the exception it throws.

Exceptions of class `Error` and `RuntimeException` and their descendants are called **unchecked exceptions**. All other exceptions are called **checked exceptions**. Unchecked exceptions are never a concern of the compiler. However, the compiler ensures that all checked exceptions a method can throw are either listed in its **`throws`** clause or handled in the method. Note that checking this at compile time differs from C++, in which it is done at run time. The reason why exceptions of the classes `Error` and `RuntimeException` and their descendants are unchecked is that any method could throw them. A program can catch unchecked exceptions, but it is not required.

As is the case with C++, a method cannot declare more exceptions in its **`throws`** clause than the method it overrides, though it may declare fewer. So if a method has no **`throws`** clause, neither can any method that overrides it. A method can throw any exception listed in its **`throws`** clause, along with any of the descendant classes of those exceptions.

A method that does not directly throw a particular exception, but calls another method that could throw that exception, must list the exception in its **throws** clause. This is the reason the `buildDist` method (in the example in the next subsection), which uses the `readLine` method, must specify `IOException` in the **throws** clause of its header.

A method that does not include a **throws** clause cannot propagate any checked exception. Recall that in C++, a function without a **throw** clause can throw *any* exception.

A method that calls a method that lists a particular checked exception in its **throws** clause has three alternatives for dealing with that exception: First, it can catch the exception and handle it. Second, it can catch the exception and throw an exception that is listed in its own **throws** clause. Third, it could declare the exception in its own **throws** clause and not handle it, which effectively propagates the exception to an enclosing **try** clause, if there is one, or to the method's caller, if there is no enclosing **try** clause.

There are no default exception handlers, and it is not possible to disable exceptions. Continuation in Java is exactly as in C++.

14.3.5 An Example

Following is the Java program with the capabilities of the C++ program in Section 14.2.5:

```
// Grade Distribution
//  Input: A list of integer values that represent
//         grades, followed by a negative number
// Output: A distribution of grades, as a percentage for
//         each of the categories 0-9, 10-19, . . .,
//         90-100.
import java.io.*;
// The exception definition to deal with the end of data
class NegativeInputException extends Exception {
  public NegativeInputException() {
    System.out.println("End of input data reached");
  }  //** end of constructor
}  //** end of NegativeInputException class
```

```
class GradeDist {
  int newGrade,
      index,
       limit_1,
       limit_2;
  int [] freq = {0, 0, 0, 0, 0, 0, 0, 0, 0, 0};
void buildDist() throws  IOException {
  DataInputStream in =  new  DataInputStream(System.in);
  try {
    while (true) {
      System.out.println("Please input a grade");
      newGrade = Integer.parseInt(in.readLine());
      if (newGrade < 0)
        throw new NegativeInputException();
      index = newGrade / 10;
      try {
        freq[index]++;
      }  //** end of inner try clause
      catch(ArrayIndexOutOfBoundsException e) {
        if (newGrade == 100)
          freq [9]++;
        else
          System.out.println("Error - new grade: " +
                     newGrade + " is out of range");
      }  //** end of catch (ArrayIndex. . .
    }  //** end of while (true) . . .
  }  //** end of outer try clause
  catch(NegativeInputException e) {
    System.out.println ("\nLimits    Frequency\n");
    for (index = 0; index < 10; index++) {
      limit_1 = 10 * index;
      limit_2 = limit_1 + 9;
      if (index == 9)
        limit_2 = 100;
      System.out.println("" + limit_1 + " - " +
                      limit_2 + "     " + freq [index]);
    }  //** end of for (index = 0; ...
  }  //** end of catch (NegativeInputException ...
}  //** end of method buildDist
```

The exception for a negative input, `NegativeInputException`, is defined in the program. Its constructor displays a message when an object of the class is created. Its handler produces the output of the method. `ArrayIndexOutOfBoundsException` is a predefined unchecked exception that is thrown by the Java run-time system. In both of these cases, the handler does not include an object name in its parameter. In neither case would a

name serve any purpose. Although all handlers get objects as parameters, they often are not useful.

14.3.6 The `finally` Clause

There are some situations in which a process must be executed regardless of whether a **`try`** clause throws an exception or the exception is handled in the method. One example of such a situation is a file that must be closed. Another is if the method has some external resource that must be freed in the method regardless of how the execution of the method terminates. The **`finally`** clause was designed for these kinds of needs. A **`finally`** clause is placed at the end of the list of handlers just after a complete **`try`** construct. In general, the **`try`** construct and its **`finally`** clause appear as

```
try {
  . . .
}
catch (. . .) {
  . . .
}
. . . //** More handlers
finally  {
  . . .
}
```

The semantics of this construct is as follows: If the **`try`** clause throws no exceptions, the **`finally`** clause is executed before execution continues after the **`try`** construct. If the **`try`** clause throws an exception and it is caught by a following handler, the **`finally`** clause is executed after the handler completes its execution. If the **`try`** clause throws an exception but it is not caught by a handler following the **`try`** construct, the **`finally`** clause is executed before the exception is propagated.

A **`try`** construct with no exception handlers can be followed by a **`finally`** clause. This makes sense, of course, only if the compound statement has a **`throw`**, **`break`**, **`continue`**, or **`return`** statement. Its purpose in these cases is the same as when it is used with exception handling. For example, consider the following:

```
try {
  for (index = 0; index < 100; index++) {
    . . .
    if (. . . ) {
      return;
    }  //** end of if
    . . .
  }  //** end of for
}  //** end of try clause
finally  {
 . . .
}  //** end of try construct
```

The **finally** clause here will be executed, regardless of whether the **return** terminates the loop or it ends normally.

14.3.7 Assertions

In the discussion of Plankalkül in Chapter 2, we mentioned that it included assertions. Assertions were added to Java in version 1.4. To use them, it is necessary to enable them by running the program with the `enableassertions` (or `ea`) flag, as in

```
java -enableassertions MyProgram
```

There are two possible forms of the **assert** statement:

assert condition;

assert condition : expression;

In the first case, the condition is tested when execution reaches the **assert**. If the condition evaluates to true, nothing happens. If it evaluates to false, the `AssertionError` exception is thrown. In the second case, the action is the same, except that the value of the expression is passed to the `AssertionError` constructor as a string and becomes debugging output.

The **assert** statement is used for defensive programming. A program may be written with many **assert** statements, which ensure that the program's

computation is on track to produce correct results. Many programmers put in such checks when they write a program, as an aid to debugging, even though the language they are using does not support assertions. When the program is sufficiently tested, these checks are removed. The advantage of **`assert`** statements, which have the same purpose, is that they can be disabled without removing them from the program. This saves the effort of removing them and also allows their use during subsequent program maintenance.

14.3.8 Evaluation

The Java mechanisms for exception handling are an improvement over the C++ version on which they are based.

First, a C++ program can throw any type defined in the program or by the system. In Java, only objects that are instances of `Throwable` or some class that descends from it can be thrown. This separates the objects that can be thrown from all of the other objects (and nonobjects) that inhabit a program. What significance can be attached to an exception that causes an **`int`** value to be thrown?

Second, a C++ program unit that does not include a **`throw`** clause can throw any exception, which tells the reader nothing. A Java method that does not include a **`throws`** clause cannot throw any checked exception that it does not handle. Therefore, the reader of a Java method knows from its header what exceptions it could throw but does not handle. A C++ compiler ignores **`throw`** clauses, but a Java compiler ensures that all exceptions that a method can throw are listed in its **`throws`** clause.

Third, the **`finally`** clause is a useful addition. It allows cleanup kinds of actions to take place regardless of how a compound statement terminated.

Finally, the Java run-time system implicitly throws a variety of predefined exceptions, such as for array indices out of range and dereferencing null references, which can be handled by any user program. A C++ program can handle only those exceptions that it explicitly throws (or that are thrown by library classes it uses).

C# includes exception-handling constructs that are very much like those of Java, except that C# does not have a **`throws`** clause.

14.4 Exception Handling in Python and Ruby

This section provides brief overviews of the exception-handling mechanisms of Python and Ruby.

14.4.1 Python

In Python, exceptions are objects. The base class of all exception classes is `BaseException`, from which the `Exception` class is derived. `BaseException` provides some services that are useful for all exception classes, but it is not usually directly subclassed. All predefined exception classes are derived from `Exception` and user-defined exception classes also are derived from it. The most commonly used predefined subclasses of `Exception` are `ArithmeticError`, whose primary subclasses are `OverflowError`, `ZeroDivisionError`, and `FloatingPointError`, and `LookupError`, whose main subclasses are `IndexError` and `KeyError`.

The statements for dealing with exceptions are similar to those of Java. The general form of a **`try`** construct is as follows:

```
try:
  The try block (the range of statements to be watched for except
except Exception1:
  Handler for Exception1
except Exception2:
  Handler for Exception2
...
else:
  The else block (what to do when no exception is raised)
finally:
  The finally block (what must be done regardless of what happene
```

Both the **`else`** and the **`finally`** clauses are optional.

One difference between handlers in Java and Python is that Python uses **except** to introduce them, rather than **catch**. The **else** clause is executed if no exception is raised in the **try** block. The **finally** clause has the same semantics as its counterpart in Java: If an exception is raised in the **try** block but is not handled by an immediately following handler, the exception is propagated after the **finally** block is executed. Because a handler handles its named exception, as well as all subclasses of that exception, a handler that names `Exception` handles all predefined and user-defined exceptions.

An unhandled exception is propagated to progressively larger enclosing **try** constructs, searching for an appropriate handler. If none is found, the exception is propagated to the function's caller, again searching for a handler in a nesting **try** construct. If no handler is found at any level, the default handler is called, which produces an error message and a stack trace and terminates the program.

The **raise** statement of Python is similar to the **throw** statement of Java and C++. The parameter for **raise** is the class name of the exception to be raised. For example, we could have the following:

```
raise IndexError
```

This statement implicitly creates an instance of the named class, `IndexError`.

An exception handler can gain access to the object of the raised exception by providing an **as** clause and a variable name, as in the following:

```
except Exception as ex_obj:
```

This is a universal handler, as it handles all exceptions. The exception object can be printed with a **print** statement in the handler, which produces the message of the object. For example, if the exception was `ZeroDivisionError`, the message would be `division by zero`.

Python's **assert** statement provides a mechanism for making some exception handling optional. The general form of **assert** is as follows:

```
assert test, data
```

In this statement, `test` is a Boolean flag or expression and `data` is the value that is sent to the constructor for the exception object to be raised. The meaning of this statement, which optionally raises the `AssertionError` exception, can be described with the following code:

```
if __debug__:
  if not test:
    raise AssertionError(data)
```

`__debug__` is a predefined flag that is set to `True` unless the `-0` flag is used on the command that runs the program. This allows one to disable all **`assert`** statements for a particular run of the program. If an `AssertionError` exception is not handled by the program, like other unhandled exceptions, it terminates the program after using the default handler.

Python does not have an equivalent to the **`throws`** clause of Java.

14.4.2 Ruby

Like Python, Ruby exceptions are objects and it has a large collection of predefined exception classes. All of the exceptions that are handled by application programs are either objects of the `StandardError` class or a class that descends from it. `StandardError` is derived from `Exception`, which provides two useful methods to all its descendants. These are `message`, which returns the human-readable error message, and `backtrace`, which returns a stack trace starting from the method where the exception was raised. Some of the predefined subclasses of `StandardError` are `ArgumentError`, `IndexError`, `IOError`, and `ZeroDivisionError`.

Exceptions are explicitly raised with the `raise` method. `raise` is often called with a string parameter. In this case, it raises a new `RuntimeError` object with the string as its message. For example, we could have the following:

```
raise "bad parameter"  if  count == 0
```

`raise` could also have two parameters, the first of which would be an object of an exception class. The `exception` method of this object is called and the

returned `Exception` object is raised. In this case, the second parameter would be the string message to be displayed. For example, we could have the following:

```
raise TypeError, "Float parameter expected"
if not param.is_a? Float
```

An exception handler is specified with a **`rescue`** clause, which is attached to a statement. To attach an exception handler to a segment of code, the code is placed in a **`begin-end`** block. The **`rescue`** clause is placed in the block after the code of the block. In general, this appears as in the following:

```
begin
  The sequence of statements in the block
rescue
  The handler
end
```

A **`begin-end`** block can include an **`else`** clause and/or an **`ensure`** clause. The **`else`** clause is exactly like that of Python. The **`ensure`** clause is exactly like a `finally` clause. A method can act as a container for exception handling in place of a **`begin-end`** block.

In a clear departure from most other languages, Ruby allows a segment of code that raised an exception to be rerun after the exception is handled. This is specified with a **`retry`** statement at the end of the handler.

14.5 Introduction to Event Handling

Event handling is similar to exception handling. In both cases, the handlers are implicitly called by the occurrence of something, either an exception or an event. While exceptions can be raised either explicitly by user code or implicitly by hardware or a software interpreter, events are created by external actions, such as user interactions through a graphical user interface (GUI). In this section, the fundamentals of event handling, which are less complex than those of exception handling, are introduced.

In conventional (non-event-driven) programming, the program code itself specifies the order in which that code is executed, although the order is usually affected by the program's input data. In event-driven programming, parts of the program are executed at completely unpredictable times, often triggered by user interactions with the executing program.

The particular kind of event handling discussed in this chapter is related to GUIs. Therefore, most of the events are caused by user interactions through graphical objects or components, often called *widgets*. The most common widgets are buttons. Implementing reactions to user interactions with GUI components is the most common form of event handling.

An **event** is a notification that something specific has occurred, such as a mouse click on a graphical button. Strictly speaking, an event is an object that is implicitly created by the run-time system in response to a user action, at least in the context in which event handling is being discussed here.

An **event handler** is a segment of code that is executed in response to the appearance of an event. Event handlers enable a program to be responsive to user actions.

Although event-driven programming was being used long before GUIs appeared, it has become a widely used programming methodology only in response to the popularity of these interfaces. As an example, consider the GUIs presented to users of Web browsers. Many Web documents presented

to browser users are now dynamic. Such a document may present an order form to the user, who chooses the merchandise by clicking buttons. The required internal computations associated with these button clicks are performed by event handlers that react to the click events.

Another common use of event handlers is to check for simple errors and omissions in the elements of a form, either when they are changed or when the form is submitted to the Web server for processing. Using event handling on the browser to check the validity of form data saves the time of sending that data to the server, where their correctness then must be checked by a server-resident program or script before they can be processed. This kind of event-driven programming is often done using a client-side scripting language, such as JavaScript.

14.6 Event Handling with Java

In addition to Web applications, non-Web Java applications can present GUIs to users. GUIs in Java applications are discussed in this section.

The initial version of Java provided a somewhat primitive form of support for GUI components. In version 1.2 of the language, released in late 1998, a new collection of components was added. These were collectively called Swing.

14.6.1 Java Swing GUI Components[4]

4. Over the last few years, Swing is slowly being replaced by a new GUI toolset named JAVAFX.

The Swing collection of classes and interfaces, defined in `javax.swing`, includes GUI components, or widgets. Because our interest here is event handling, not GUI components, we discuss only two kinds of widgets: text boxes and radio buttons.

A text box is an object of class `JTextField`. The simplest `JTextField` constructor takes a single parameter, the length of the box in characters. For example,

```
JTextField name = new JTextField(32);
```

The `JTextField` constructor can also take a literal string as an optional first parameter. This string parameter, when present, is displayed as the initial contents of the text box.

Radio buttons are special buttons that are placed in a button group container. A button group is an object of class `ButtonGroup`, whose constructor takes no parameters. In a radio button group, only one button can be pressed at a time.

If any button in the group becomes pressed, the previously pressed button is implicitly unpressed. The `JRadioButton` constructor, used for creating radio buttons, takes two parameters: a label and the initial state of the radio button (`true` or `false`, for pressed and not pressed, respectively). If one radio button in a group is initially set to pressed, the others in the group default to unpressed. After the radio buttons are created, they are placed in their button group with the `add` method of the group object. Consider the following example:

```
ButtonGroup payment = new ButtonGroup();
JRadioButton box1 = new JRadioButton("Visa", true);
JRadioButton box2 = new JRadioButton("Master Charge");
JRadioButton box3 = new JRadioButton("Discover");
payment.add(box1);
payment.add(box2);
payment.add(box3);
```

A `JFrame` object is a frame, which is displayed as a separate window. The `JFrame` class defines the data and methods that are needed for frames. So, a class that uses a frame can be a subclass of `JFrame`. A `JFrame` has several layers called **panes**. We are interested in just one of those layers, the content pane. Components of a GUI are placed in a `JPanel` object (a panel), which is used to organize and define the layout of the components. A frame is created and the panel containing the components is added to that frame's content pane.

Predefined graphic objects, such as GUI components, are placed directly in a panel. The following creates the panel object used in the following discussion of components:

```
JPanel myPanel = new JPanel();
```

After the components have been created with constructors, they are placed in the panel with the `add` method, as in

```
myPanel.add(button1);
```

14.6.2 The Java Event Model

When a user interacts with a GUI component, for example by clicking a button, the component creates an event object and calls an event handler through an object called an event listener, passing the event object. The event handler provides the associated actions. GUI components are event generators. In Java, events are connected to event handlers through **event listeners**. Event listeners are connected to event generators through event listener registration. Listener registration is done with a method of the class that implements the listener interface, as described later in this section. Only event listeners that are registered for a specific event are notified when that event occurs.

The listener method that receives the message implements an event handler. To make the event-handling methods conform to a standard protocol, an interface is used. An interface prescribes standard method protocols but does not provide implementations of those methods.

A class that needs to implement an event handler must implement an interface for the listener for that handler. There are several classes of events and listener interfaces. One class of events is `ItemEvent`, which is associated with the event of clicking a checkbox or a radio button, or selecting a list item. The `ItemListener` interface includes the protocol of a method, `itemStateChanged`, which is the handler for `ItemEvent` events. So, to provide an action that is triggered by a radio button click, the interface `ItemListener` must be implemented, which requires a definition of the method, `itemStateChanged`.

As stated previously, the connection of a component to an event listener is made with a method of the class that implements the listener interface. For example, because `ItemEvent` is the class name of event objects created by user actions on radio buttons, the `addItemListener` method is used to register a listener for radio buttons. The listener for button events created in a panel could be implemented in the panel or a subclass of `JPanel`. So, for a radio button named `button1` in a panel named `myPanel` that implements the `ItemEvent` event handler for buttons, we would register the listener with the following statement:

```
button1.addItemListener(this);
```

Each event handler method receives an event parameter, which provides information about the event. Event classes have methods to access that information. For example, when called through a radio button, the `isSelected` method returns **`true`** or **`false`**, depending on whether the button was on or off (pressed or not pressed), respectively.

All the event-related classes are in the `java.awt.event` package, so it is imported to any class that uses events.

The following is an example application, `RadioB`, that illustrates the use of events and event handling. This application constructs radio buttons that control the font style of the contents of a text field. It creates a `Font` object for each of four font styles. Each of these has a radio button to enable the user to select the font style.

The purpose of this example is to show how events raised by GUI components can be handled to change the output display of the program dynamically. Because of our narrow focus on event handling, some parts of this program are not explained here.

```
/* RadioB.java
   An example to illustrate event handling with interactive
   radio buttons that control the font style of a textfield
  */
package radiob;
import java.awt.*;
import java.awt.event.*;
import javax.swing.*;
public class RadioB extends JPanel implements
        ItemListener {
    private JTextField text;
    private Font plainFont, boldFont, italicFont,
                 boldItalicFont;
    private JRadioButton plain, bold, italic, boldItalic;
    private ButtonGroup radioButtons;
// The constructor method is where the display is initially
//  built
    public  RadioB() {
// Create the test text string and set its font
        text = new JTextField(
             "In what font style should I appear?", 25);
        text.setFont(plainFont);
// Create radio buttons for the fonts and add them to
```

```
//  a new button group
        plain = new JRadioButton("Plain", true);
        bold = new JRadioButton("Bold");
        italic = new JRadioButton("Italic");
        boldItalic = new JRadioButton("Bold Italic");
        radioButtons = new ButtonGroup();
        radioButtons.add(plain);
        radioButtons.add(bold);
        radioButtons.add(italic);
        radioButtons.add(boldItalic);
        // Create a panel and put the text and the radio
        //  buttons in it; then add the panel to the frame
        JPanel radioPanel = new JPanel();
        radioPanel.add(text);
        radioPanel.add(plain);
        radioPanel.add(bold);
        radioPanel.add(italic);
        radioPanel.add(boldItalic);
        add(radioPanel, BorderLayout.LINE_START);
// Register the event handlers
        plain.addItemListener(this);
        bold.addItemListener(this);
        italic.addItemListener(this);
        boldItalic.addItemListener(this);
// Create the fonts
        plainFont = new Font("Serif", Font.PLAIN, 16);
        boldFont = new Font("Serif", Font.BOLD, 16);
        italicFont = new Font("Serif", Font.ITALIC, 16);
        boldItalicFont = new  Font("Serif", Font.BOLD +
                                   Font.ITALIC, 16);
    }  // End of the constructor for RadioB
// The event handler
    public void itemStateChanged (ItemEvent e) {
// Determine which button is on and set the font
//  accordingly
       if (plain.isSelected())
          text.setFont(plainFont);
       else if (bold.isSelected())
          text.setFont(boldFont);
       else if (italic.isSelected())
          text.setFont(italicFont);
       else if  (boldItalic.isSelected())
          text.setFont(boldItalicFont);
    } // End of itemStateChanged
// The main method
     public static void main(String[] args) {
// Create the window frame
        JFrame myFrame = new JFrame(" Radio button
```

```
                                          example");
// Create the content pane and set it to the frame
        JComponent myContentPane = new RadioB();
        myContentPane.setOpaque(true);
        myFrame.setContentPane(myContentPane);
// Display the window.
        myFrame.pack();
        myFrame.setVisible(true);
    }
} // End of RadioB
```

The `RadioB.java` application produces the screen shown in Figure 14.2.

14.7 Event Handling in C#

Event handling in C# (and in the other .NET languages) is similar to that of Java. .NET provides two approaches to creating GUIs in applications, the original Windows Forms and the more recent Windows Presentation Foundation. The latter is the more sophisticated and complex of the two. Because our interest is just in event handling, we will use the simpler Windows Forms to discuss our subject.

Using Windows Forms, a C# application that constructs a GUI is created by subclassing the `Form` predefined class, which is defined in the `System.Windows.Forms` namespace. This class implicitly provides a window to contain our components. There is no need to build frames or panels explicitly.

Text can be placed in a `Label` object and radio buttons are objects of the `RadioButton` class. The size of a `Label` object is not explicitly specified in the constructor; rather it can be specified by setting the `AutoSize` data member of the `Label` object to **`true`**, which sets the size according to what is placed in it.

Components can be placed at a particular location in the window by assigning a new `Point` object to the `Location` property of the component. The `Point` class is defined in the `System.Drawing` namespace. The `Point` constructor takes two parameters, which are the coordinates of the object in pixels. For example, `Point(100, 200)` is a position that is `100` pixels from the left edge of the window and `200` pixels from the top. The label of a component is set by assigning a string literal to the `Text` property of the component. After creating a component, it is added to the form window by sending it to the `Add` method of the `Controls` subclass of the form. Therefore, the following code creates a radio button with the label `Plain` at the `(100, 300)` position in the output window:

```
private RadioButton plain = new RadioButton();
plain.Location = new Point(100, 300);
plain.Text = "Plain";
```

```
Controls.Add(plain);
```

All C# event handlers have the same protocol: the return type is **`void`** and the two parameters are of types **`object`** and `EventArgs`. Neither of the parameters needs to be used for a simple situation. An event handler method can have any name. A radio button is tested to determine whether it is clicked with the Boolean `Checked` property of the button. Consider the following skeletal example of an event handler:

```
private void rb_CheckedChanged (object o, EventArgs e){
  if (plain.Checked) . . .
  . . .
}
```

To register an event, a new `EventHandler` object must be created. The constructor for this class is sent the name of the handler method. The new object is added to the predefined delegate for the event on the component object (using the `+=` assignment operator). For example, when a radio button changes from unchecked to checked, the `CheckedChanged` event is raised and the handlers registered on the associated delegate, which is referenced by the name of the event, are called. If the event handler is named `rb_CheckedChanged`, the following statement would register the handler for the `CheckedChanged` event on the radio button `plain`:

```
plain. CheckedChanged +=
       new EventHandler(rb_CheckedChanged);
```

Following is the `RadioB` example from Section 14.6 rewritten in C#. Once again, because our focus is on event handling, we do not explain all of the details of the program.

```
// RadioB.cs
// An example to illustrate event handling with
//   interactive radio buttons that control the font
//  style of a string of text
namespace RadioB {
    using System;
    using System.Drawing;
    using System.Windows.Forms;
  public class RadioB : Form {
    private Label text = new Label();
    private RadioButton plain = new RadioButton();
```

```
private RadioButton bold = new RadioButton();
private RadioButton italic = new RadioButton();
private RadioButton boldItalic = new RadioButton();
// Constructor for RadioB
public RadioB() {
  // Initialize the attributes of the text and radio
  //  buttons
  text.AutoSize = true;
  text.Text = "In what font style should I appear?";
  plain.Location = new Point(220,0);
  plain.Text = "Plain";
  plain.Checked = true;
  bold.Location = new Point(350, 0);
  bold.Text = "Bold";
  italic.Location = new Point(480, 0);
  italic.Text = "Italics";
  boldItalic.Location = new Point(610, 0);
  boldItalic.Text = "Bold/Italics";
  // Add the text and the radio buttons to the form
  Controls.Add(text);
  Controls.Add(plain);
  Controls.Add(bold);
  Controls.Add(italic);
  Controls.Add(boldItalic);
  // Register the event handler for the radio buttons
  plain.CheckedChanged +=
       new EventHandler(rb_CheckedChanged);
  bold.CheckedChanged +=
       new EventHandler(rb_CheckedChanged);
  italic.CheckedChanged +=
       new EventHandler(rb_CheckedChanged);
  boldItalic.CheckedChanged +=
       new EventHandler(rb_CheckedChanged);
}
// The main method is where execution begins
static void Main() {
  Application.EnableVisualStyles();
  Application.SetCompatibleTextRenderingDefault (false);
  Application.Run(new RadioB());
}
// The event handler
private void rb_CheckedChanged (object o,
                                EventArgs e) {
// Determine which button is on and set the font
//  accordingly
 if (plain.Checked)
     text.Font =
          new Font( text.Font.Name, text.Font.Size,
```

```
                        FontStyle.Regular);
        if (bold.Checked)
            text.Font =
                new Font(text.Font.Name, text.Font.Size,
                        FontStyle.Bold);
        if (italic.Checked)
            text.Font =
                new Font(text.Font.Name, text.Font.Size,
                        FontStyle.Italic);
        if (boldItalic.Checked)
            text.Font =
                new Font(text.Font.Name, text.Font.Size,
                        FontStyle.Italic ^ FontStyle.Bold);
      } // End of radioButton_CheckedChanged
    } // End of RadioB
}
```

The output from this program is exactly like that shown in Figure 14.2.

SUMMARY

C++ includes no predefined exceptions (except those defined in the standard library). C++ exceptions are objects of a primitive type, a predefined class, or a user-defined class. Exceptions are bound to handlers by connecting the type of the expression in the **`throw`** statement to that of the formal parameter of the handler. Handlers all have the same name—**`catch`**. The C++ **`throw`** clause of a method lists the types of exceptions that the method could throw.

Java exceptions are objects whose ancestry must trace back to a class that descends from the `Throwable` class. There are two categories of exceptions—checked and unchecked. Checked exceptions are a concern for the user program and the compiler. Unchecked exceptions can occur anywhere and are often ignored by user programs.

The Java **`throws`** clause of a method lists the checked exceptions that it could throw and does not handle. It must include exceptions that methods it calls could raise and propagate back to its caller.

The Java **`finally`** clause provides a mechanism for guaranteeing that some code will be executed regardless of how the execution of a **`try`** compound terminates.

Java now includes an **`assert`** statement, which facilitates defensive programming.

Python's exception handling is similar to that of Java, although it adds the **`else`** clause to the **`try`** construct. Also, it uses **`except`** clauses rather than **`catch`** clauses to define handlers and **`raise`** instead of **`throw`**. Access to the data of an exception object is gained by assigning the object to a variable with an **`as`** clause. Python's **`assert`** statement is a conditional **`raise`**.

Exception handling in Ruby is similar to that of Python. Every exception class has two methods, `message` and `backtrace`. Exceptions are often raised with a **`raise`** statement with a single string parameter. This creates a new

`RuntimeError` object with the string as its message. The **`raise`** statement can be made conditional by adding a conditional expression to it. The scope of exception handlers usually is specified with a **`begin-end`** block. Handlers are defined in **`rescue`** clauses. A **`begin-end`** block can include an **`else`** clause and an **`ensure`** clause, which is like the **`finally`** clause of Python and Java.

An event is a notification that something has occurred that requires special processing. Events are often created by user interactions with a program through a graphical user interface. Java event handlers are called through event listeners. An event listener must be registered for an event if it is to be notified when the event occurs. Two of the most commonly used event listeners interfaces are `actionPerformed` and `itemStateChanged`.

Windows Forms is the original approach to building GUI components and handling events in .NET languages. A C# application builds a GUI in this approach by subclassing the `Form` class. All .NET event handlers use the same protocol. Event handlers are registered by creating an `EventHandler` object and assigning it to the predefined delegate associated with the GUI object that can raise the event.

BIBLIOGRAPHIC NOTES

One of the most important papers on exception handling that is not connected with a particular programming language is the work by Goodenough (1975). The problems with the PL/I design for exception handling are covered in MacLaren (1977). Exception handling in C++ is described by Stroustrup (1997). Exception handling in Java is described by Campione et al. (2001).

REVIEW QUESTIONS

1. Define *exception*, *exception handler*, *raising an exception*, *continuation*, *finalization*, and *built-in exception*.

2. What are the two alternatives for designing continuation?

3. What are the advantages of having support for exception handling built in to a language?

4. What are the design issues for exception handling?

5. What does it mean for an exception to be bound to an exception handler?

6. What is the name of all C++ exception handlers?

7. How can exceptions be explicitly raised in C++?

8. How are exceptions bound to handlers in C++?

9. How can an exception handler be written in C++ so that it handles any exception?

10. Where does execution control go when a C++ exception handler has completed its execution?

11. Does C++ include built-in exceptions?

12. Why is the raising of an exception in C++ not called raise?

13. What is the root class of all Java exception classes?

14. What is the parent class of most Java user-defined exception classes?

15. How can an exception handler be written in Java so that it handles any

exception?

16. What are the differences between a C++ **`throw`** specification and a Java **`throws`** clause?

17. What is the difference between checked and unchecked exceptions in Java?

18. How can an exception handler be written in Java so that it handles any exception?

19. What is the purpose of the Java **`finally`** clause?

20. What advantage do language-defined assertions have over simple **`if-then`** constructs?

21. Explain what an **`else`** block in Python does.

22. What is the purpose of an **`as`** clause in Python?

23. Explain what an **`assert`** statement in Python does.

24. What does the `message` method of Ruby's `StandardError` class do?

25. What exactly happens when a **`raise`** statement with a string parameter is executed?

26. What exactly does a Ruby **`ensure`** clause do?

27. In what ways are exception handling and event handling related?

28. Define event and event handler.

29. What is event-driven programming?

30. What is the purpose of a Java `JFrame`?

31. What is the purpose of a Java `JPanel`?

32. What object is often used as the event listener in Java GUI applications?

33. What is the origin of the protocol for an event handler in Java?

34. What method is used to register an event handler in Java?

35. Using .NET's Windows Forms, what namespace is required to build a GUI for a C# application?

36. How is a component positioned in a form using Windows Forms?

37. What is the protocol of a .NET event handler?

38. What class of object must be created to register a .NET event handler?

39. What role do delegates play in the process of registering event handlers?

PROBLEM SET

1. What did the designers of C get in return for not requiring subscript range checking?

2. Describe three approaches to exception handling in languages that do not provide direct support for it.

3. From textbooks on the PL/I and Ada programming languages, look up the respective sets of built-in exceptions. Do a comparative evaluation of the two, considering both completeness and flexibility.

4. From a textbook on COBOL, determine how exception handling is done in COBOL programs.

5. In languages without exception-handling facilities, it is common to have most subprograms include an "error" parameter, which can be set to some value representing "OK" or some other value representing "error in procedure." What advantage does a linguistic exception-handling facility like that of Java have over this method?

6. In a language without exception-handling facilities, we could send an error-handling procedure as a parameter to each procedure that can detect errors that must be handled. What disadvantages are there to this method?

7. Compare the methods suggested in Problems 5 and 6. Which do you think is better and why?

8. Write a comparative analysis of the **`throw`** clause of C++ and the **`throws`** clause of Java.

9. Consider the following C++ skeletal program:

```
class Big {
  int i;
```

```
  float f;
  void fun1() throw int {
      . . .
      try {
        . . .
        throw i;
      . . .
      throw f;
      . . .
    }
    catch(float) { . . . }
  . . .
  }
}
class Small {
  int j;
  float g;
  void fun2() throw float {
    . . .
    try {
      . . .
      try {
        Big.fun1();
        . . .
        throw j;
        . . .
        throw g;
        . . .
     }
     catch(int) { . . . }
     . . .
    }
    catch(float) { . . . }
  }
}
```

In each of the four **`throw`** statements, where is the exception handled? Note that `fun1` is called from `fun2` in class `Small`.

10. Write a detailed comparison of the exception-handling capabilities of C++ and those of Java.

11. With the help of a book on ML, write a detailed comparison of the exception-handling capabilities of ML and those of Java.

12. Summarize the arguments in favor of the termination and resumption models of continuation.

PROGRAMMING EXERCISES

1. Suppose you are writing a C++ function that has three alternative approaches for accomplishing its requirements. Write a skeletal version of this function so that if the first alternative raises any exception, the second is tried, and if the second alternative raises any exception, the third is executed. Write the code as if the three methods were procedures named `alt1`, `alt2`, and `alt3`.

2. Write a Java program that inputs a list of integer values in the range of −100 to 100 from the keyboard and computes the sum of the squares of the input values. This program must use exception handling to ensure that the input values are in range and are legal integers, to handle the error of the sum of the squares becoming larger than a standard `Integer` variable can store, and to detect end-of-file and use it to cause the output of the result. In the case of overflow of the sum, an error message must be printed and the program terminated.

3. Write a C++ program for the specification of Programming Exercise 2.

4. Revise the Java program of Section 14.3.5 to use `EOFException` to detect the end of the input.

5. Rewrite the Java code of Section 14.3.6 that uses a **`finally`** clause in C++.

15 Functional Programming Languages

This chapter introduces functional programming and some of the programming languages that have been designed for this approach to software development. We begin by reviewing the fundamental ideas of mathematical functions, because functional languages are based on them. Next, the idea of a functional programming language is introduced, followed by a look at the first functional language, Lisp. The next, somewhat lengthy section, is devoted to an introduction to Scheme, including some of its primitive functions, special forms, functional forms, and some examples of simple functions written in Scheme. Next, we provide brief introductions to

Common Lisp, ML, Haskell, and F#. Then, we discuss support for functional programming that is included in some imperative languages. The following section describes some of the applications of functional programming languages. Finally, we present a brief comparison of functional and imperative languages.

15.1 Introduction

Most of the earlier chapters of this book have been concerned primarily with the imperative programming languages. The high degree of similarity among the imperative languages arises in part from one of the common bases of their design: the von Neumann architecture, as discussed in Chapter 1. Imperative languages can be thought of collectively as a progression of developments to improve the basic model, which was Fortran I. All have been designed to make efficient use of von Neumann architecture computers. Although the imperative style of programming has been found acceptable by most programmers, its heavy reliance on the underlying architecture is thought by some to be an unnecessary restriction on the alternative approaches to software development.

Other bases for language design exist, some of them oriented more to particular programming paradigms or methodologies than to efficient execution on a particular computer architecture. Thus far, however, only a relatively small minority of programs have been written in nonimperative languages.

The functional programming paradigm, which is based on mathematical functions, is the design basis of the most important nonimperative styles of languages. This style of programming is supported by functional programming languages.

The 1977 ACM Turing Award was given to John Backus for his work in the development of Fortran. Each recipient of this award presents a lecture when the award is formally given, and the lecture is subsequently published in the *Communications of the ACM*. In his Turing Award lecture, Backus (1978) made a case that purely functional programming languages are better than imperative languages because they result in programs that are more readable, more reliable, and more likely to be correct. The crux of his argument was that purely functional programs are easier to understand, both during and after development, largely because the meanings of expressions are independent of their context (one characterizing feature of a pure functional

programming language is that neither expressions nor functions have side effects).

In this lecture, Backus proposed a pure functional language, FP (*f*unctional *p*rogramming), which he used to frame his argument. Although the language did not succeed, at least in terms of achieving widespread use, his idea motivated debate and research on pure functional programming languages. The point here is that some well-known computer scientists have attempted to promote the concept that functional programming languages are superior to the traditional imperative languages, though those efforts have obviously fallen short of their goals. However, over the last decade, prompted in part by the maturing of the typed functional languages, such as ML, Haskell, OCaml, and F#, there has been an increase in the interest in and use of functional programming languages.

One of the fundamental characteristics of programs written in imperative languages is that they have state, which changes throughout the execution process. This state is represented by the program's variables. The author and all readers of the program must understand the uses of its variables and how the program's state changes through execution. For a large program, this is a daunting task. This is one problem with programs written in an imperative language that is not present in a program written in a pure functional language, for such programs have neither variables nor state.

Lisp began as a pure functional language but soon acquired some important imperative features that increased its execution efficiency. It is still the most important of the functional languages, at least in the sense that it is the only one that has achieved widespread use. It dominates in the areas of knowledge representation, machine learning, intelligent training systems, and the modeling of speech. Common Lisp is an amalgam of several early 1980s dialects of Lisp.

Scheme is a small, static-scoped dialect of Lisp. Scheme has been widely used to teach functional programming. It is also used in some universities to teach introductory programming courses.

The development of the typed functional programming languages, primarily ML, Haskell, OCaml, and F#, has led to a significant expansion of the areas

of computing in which functional languages are now used. As these languages have matured, their practical use is growing. They are now being used in areas such as database processing, financial modeling, statistical analysis, and bioinformatics.

One objective of this chapter is to provide an introduction to functional programming using the core of Scheme, intentionally leaving out its imperative features. Sufficient material on Scheme is included to allow the reader to write some simple but interesting programs. It is difficult to acquire an actual feel for functional programming without some actual programming experience, so that is strongly encouraged.

15.2 Mathematical Functions

A mathematical function is a mapping of members of one set, called the **domain set**, to another set, called the **range set**. A function definition specifies the domain and range sets, either explicitly or implicitly, along with the mapping. The mapping is described by an expression or, in some cases, by a table. Functions are often applied to a particular element of the domain set, given as a parameter to the function. Note that the domain set may be the cross product of several sets (reflecting that there can be more than one parameter). A function yields an element of the range set.

One of the fundamental characteristics of mathematical functions is that the evaluation order of their mapping expressions is controlled by recursion and conditional expressions, rather than by the sequencing and iterative repetition that are common to programs written in the imperative programming languages.

Another important characteristic of mathematical functions is that because they have no side effects and cannot depend on any external values, they always map a particular element of the domain to the same element of the range. However, a subprogram in an imperative language may depend on the current values of several nonlocal or global variables. This makes it difficult to determine statically what values the subprogram will produce and what side effects it will have on a particular execution.

In mathematics, there is no such thing as a variable that models a memory location. Local variables in functions in imperative programming languages maintain the state of the function. Computation is accomplished by evaluating expressions in assignment statements that change the state of the program. In mathematics, there is no concept of the state of a function.

A mathematical function maps its parameter(s) to a value (or values), rather than specifying a sequence of operations on values in memory to produce a value.

15.2.1 Simple Functions

Function definitions are often written as a function name, followed by a list of parameters in parentheses, followed by the mapping expression. For example,

cube(x)≡x * x * x, where x is a real number.

In this definition, the domain and range sets are the real numbers. The symbol ≡ is used to mean “is defined as.” The parameter x can represent any member of the domain set, but it is fixed to represent one specific element during evaluation of the function expression. This is one way the parameters of mathematical functions differ from the variables in imperative languages.

Function applications are specified by pairing the function name with a particular element of the domain set. The range element is obtained by evaluating the function-mapping expression with the domain element substituted for the occurrences of the parameter. Once again, it is important to note that during evaluation, the mapping of a function contains no unbound parameters, where a bound parameter is a name for a particular value. Every occurrence of a parameter is bound to a value from the domain set and is a constant during evaluation. For example, consider the following evaluation of cube(x):

cube (2.0)=2.0 * 2.0 * 2.0=8

The parameter x is bound to 2.0 during the evaluation and there are no unbound parameters. Furthermore, x is a constant (its value cannot be changed) during the evaluation.

Early theoretical work on functions separated the task of defining a function from that of naming the function. Lambda notation, as devised by Alonzo Church (1941), provides a method for defining nameless functions. A **lambda expression** specifies the parameters and the mapping of a function. The lambda expression is the function itself, which is nameless. For example, consider the following lambda expression:

λ(x)x * x * x

Church defined a formal computation model (a formal system for function definition, function application, and recursion) using lambda expressions. This is called **lambda calculus**. Lambda calculus can be either typed or untyped. Untyped lambda calculus serves as the inspiration for the functional programming languages.

As stated earlier, before evaluation a parameter represents any member of the domain set, but during evaluation it is bound to a particular member. When a lambda expression is evaluated for a given parameter, the expression is said to be applied to that parameter. The mechanics of such an application are the same as for any function evaluation. Application of the example lambda expression is denoted as in the following example:

(λ(x)x * x * x)(2)

which results in the value 8.

Lambda expressions, like other function definitions, can have more than one parameter.

15.2.2 Functional Forms

A **higher-order function**, or **functional form**, is one that either takes one or more functions as parameters or yields a function as its result, or both. One common kind of functional form is **function composition**, which has two functional parameters and yields a function whose value is the first actual parameter function applied to the result of the second. Function composition is written as an expression, using º as an operator, as in

h≡f ° g

For example, if

f(x)≡x+2 g(x)≡3*x

then *h* is defined as

h(x)≡f(g(x)), or h(x)≡(3*x)+2

Apply-to-all is a functional form that takes a single function as a parameter.[1] If applied to a list of parameters, apply-to-all applies its functional parameter to each of the values in the list parameter and collects the results in a list or sequence. Apply-to-all is denoted by α. Consider the following example:

1. In programming languages, these are often called *map* functions.

Let

h(x)≡x*x

then

α(h,(2,3,4)) yields `(4, 9, 16)`

There are other functional forms, but these two examples illustrate the basic characteristics of all of them.

15.3 Fundamentals of Functional Programming Languages

The objective of the design of a functional programming language is to mimic mathematical functions to the greatest extent possible. This results in an approach to problem solving that is fundamentally different from approaches used with imperative languages. In an imperative language, an expression is evaluated and the result is stored in a memory location, which is represented as a variable in a program. This is the purpose of assignment statements. This necessary attention to memory cells, whose values represent the state of the program, results in a relatively low-level programming methodology.

A program in an assembly language often must also store the results of partial evaluations of expressions. For example, to evaluate

$(x+y)/(a-b)$

the value of $(x+y)$ is computed first. That value must then be stored while $(a-b)$ is evaluated. The compiler handles the storage of intermediate results of expression evaluations in high-level languages. The storage of intermediate results is still required, but the details are hidden from the programmer.

A purely functional programming language does not use variables or assignment statements, thus freeing the programmer from concerns related to the memory cells, or state, of the program. Without variables, iterative constructs are not possible, for they are controlled by variables. Repetition must be specified with recursion rather than with iteration. Programs are function definitions and function application specifications, and executions consist of evaluating function applications. Without variables, the execution of a purely functional program has no state in the sense of operational and denotational semantics. The execution of a function always produces the same result when given the same parameters. This characteristic is called **referential transparency**. It makes the semantics of purely functional

languages far simpler than the semantics of the imperative languages (and the functional languages that include imperative features). It also makes testing easier, because each function can be tested separately, without any concern for its context.

A functional language provides a set of primitive functions, a set of functional forms to construct complex functions from those primitive functions, a function application operation, and some structure or structures for representing data. These structures are used to represent the parameters and values computed by functions. If a functional language is well designed, it requires only a relatively small number of primitive functions.

As we have seen in earlier chapters, the first functional programming language, Lisp, uses a syntactic form for both data and code that is very different from that of the imperative languages. However, many functional languages designed later use syntax for their code that is similar to that of the imperative languages.

Although there are a few purely functional languages, for example, Haskell, most of the languages that are called functional include some imperative features, for example, mutable variables and constructs that act as assignment statements.

Some concepts and constructs that originated in functional languages, such as lazy evaluation and anonymous subprograms, have now found their way into some languages that are considered imperative.

Although early functional languages were often implemented with interpreters, many programs written in functional programming languages are now compiled.

15.4 The First Functional Programming Language: Lisp

Many functional programming languages have been developed. The oldest and most widely used is Lisp (or one of its descendants), which was developed by John McCarthy at MIT in 1959. Studying functional languages through Lisp is somewhat akin to studying the imperative languages through Fortran: Lisp was the first functional language, but although it has steadily evolved for half a century, it no longer represents the latest design concepts for functional languages. In addition, with the exception of the first version, all Lisp dialects include imperative-language features, such as imperative-style variables, assignment statements, and iteration. (Imperative-style variables are used to name memory cells, whose values can change many times during program execution.) Despite this and their somewhat odd form, the descendants of the original Lisp represent well the fundamental concepts of functional programming and are therefore worthy of study.

15.4.1 Data Types and Structures

There were only two categories of data objects in the original Lisp: atoms and lists. List elements are pairs, where the first part is the data of the element, which is a pointer to either an atom or a nested list. The second part of a pair can be a pointer to an atom, a pointer to another element, or a special value, nil. Elements are linked together in lists with the second parts. Atoms and lists are not types in the sense that imperative languages have types. In fact, the original Lisp was a typeless language. Atoms are either symbols, in the form of identifiers, or numeric literals.

Recall from Chapter 2, that Lisp originally used lists as its data structure because they were thought to be an essential part of list processing. As it eventually developed, however, Lisp rarely requires the general list operations of insertion and deletion at positions other than the beginning of a

list.

Lists are specified in Lisp by delimiting their elements with parentheses. The elements of **simple lists** are restricted to atoms, as in

```
(A B C D)
```

Nested list structures are also specified by parentheses. For example, the list

```
(A (B C) D (E (F G)))
```

is a list of four elements. The first is the atom `A`; the second is the sublist `(B C)`; the third is the atom `D`; the fourth is the sublist `(E (F G))`, which has as its second element the sublist `(F G)`.

In a Lisp implementation, a list is usually stored as linked list structure in which each node has two pointers, one to reference the data of the node and the other to form the linked list. A list is referenced by a pointer to its first element.

The internal representations of our two example lists are shown in Figure 15.1. Note that the elements of a list are shown horizontally. The last element of a list has no successor, so its link is nil. Sublists are shown with the same structure.

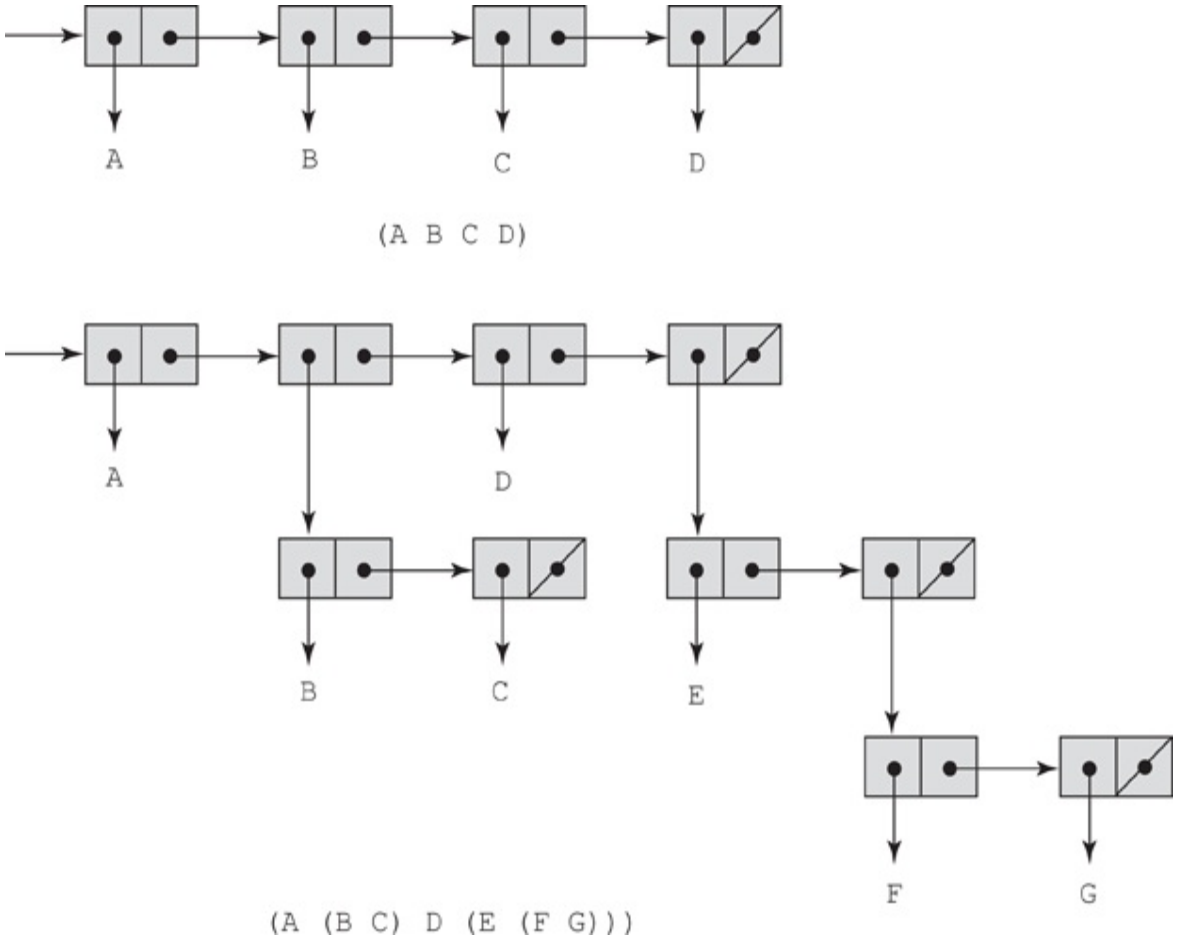

Figure 15.1 Internal representation of two Lisp lists

15.4.2 The First Lisp Interpreter

The original intent of Lisp's design was to have a notation for programs that would be as close to Fortran's as possible, with additions when necessary. This notation was called M-notation, for meta-notation. There was to be a compiler that would translate programs written in M-notation into semantically equivalent machine code programs for the IBM 704.

Early in the development of Lisp, McCarthy wrote a paper to promote list processing as an approach to general symbolic processing. McCarthy believed that list processing could be used to study computability, that at the time was usually studied using Turing machines, which are based on the imperative model of computation. McCarthy thought that the functional processing of symbolic lists was a more natural model of computation than Turing machines, that operated on symbols written on tapes, which represented state. One of the common requirements of the study of computation is that one must be able to prove certain computability characteristics of the whole class of whatever model of computation is being used. In the case of the Turing machine model, one can construct a universal Turing machine that can mimic the operations of any other Turing machine. From this concept came the idea of constructing a universal Lisp function that could evaluate any other function in Lisp.

The first requirement for the universal Lisp function was a notation that allowed functions to be expressed in the same way data was expressed. The parenthesized list notation described in Section 15.4.1 had already been adopted for Lisp data, so it was decided to invent conventions for function definitions and function calls that could also be expressed in list notation. Function calls were specified in a prefix list form originally called **Cambridge Polish**,2 as in the following:

2. This name first was used in the early development of Lisp. The name was chosen because Lisp lists resemble the prefix notation used by the Polish logician Jan Lukasiewicz, and because Lisp was born at MIT in Cambridge, Massachusetts. Some now prefer to call the notation *Cambridge prefix*.

(function_name parameter1 . . . cparametern)

For example, if + is a function that takes two or more numeric parameters, the following two expressions evaluate to `12` and `20`, respectively:

```
(+ 5 7)
(+ 3 4 7 6)
```

The lambda notation described in Section 15.2.1 was chosen to specify function definitions. It had to be modified, however, to allow the binding of

functions to names so that functions could be referenced by other functions and by themselves. This name binding was specified by a list consisting of the function name and a list containing the lambda expression, as in

```
(function_name (LAMBDA ( param1...paramn) expression))
```

If you have had no prior exposure to functional programming, it may seem odd to even consider a nameless function. However, nameless functions are sometimes useful in functional programming (as well as in mathematics and imperative programming). For example, consider a function whose action is to produce a function for immediate application to a parameter list. The produced function has no need for a name, for it is applied only at the point of its construction. Such an example is given in Section 15.5.14.

Lisp functions specified in this new notation were called S-expressions, for *s*ymbolic expressions. Eventually, all Lisp structures, both data and code, were called S-expressions. An S-expression can be either a list or an atom. We will usually refer to S-expressions simply as expressions.

McCarthy successfully developed a universal function that could evaluate any other function. This function was named EVAL and was itself in the form of an expression. Two of the people in the AI Project, which was developing Lisp, Stephen B. Russell and Daniel J. Edwards, noticed that an implementation of EVAL could serve as a Lisp interpreter, and they promptly constructed such an implementation (McCarthy et al., 1965).

There were several important results of this quick, easy, and unexpected implementation. First, all early Lisp implementations copied EVAL and were therefore interpretive. Second, the definition of M-notation, which was the planned programming notation for Lisp, was never completed or implemented, so S-expressions became Lisp's only notation. The use of the same notation for data and code has important consequences, one of which will be discussed in Section 15.5.14. Third, much of the original language design was effectively frozen, keeping certain odd features in the language, such as the conditional expression form and the use of () for both the empty list and logical false.

Another feature of early Lisp systems that was apparently accidental was the

use of dynamic scoping. Functions were evaluated in the environments of their callers. No one at the time knew much about scoping, and there may have been little thought given to the choice. Dynamic scoping was used for most dialects of Lisp before 1975. Contemporary dialects either use static scoping or allow the programmer to choose between static and dynamic scoping.

An interpreter for Lisp can be written in Lisp. Such an interpreter, which is not a large program, describes the operational semantics of Lisp, in Lisp. This is vivid evidence of the semantic simplicity of the language.

15.5 An Introduction to Scheme

In this section, we describe the core part of Scheme (Dybvig, 2011). We have chosen Scheme because it is relatively simple, it is popular in colleges and universities, and Scheme interpreters are readily available (and free) for a wide variety of computers. The version of Scheme described in this section is Scheme 4. Note that this section covers only a small part of Scheme, and it includes none of Scheme's imperative features.

15.5.1 Origins of Scheme

The Scheme language, which is a dialect of Lisp, was developed at MIT in the mid-1970s (Sussman and Steele, 1975). It is characterized by its small size, its exclusive use of static scoping, and its treatment of functions as first-class entities. As first-class entities, Scheme functions can be the values of expressions, elements of lists, passed as parameters, and returned from functions. Early versions of Lisp did not provide all of these capabilities.

As an essentially typeless small language with simple syntax and semantics, Scheme is well suited to educational applications, such as courses in functional programming, and also to general introductions to programming.

Most of the Scheme code in the following sections would require only minor modifications to be converted to valid Lisp code.

15.5.2 The Scheme Interpreter

A Scheme interpreter in interactive mode is an infinite read-evaluate-print loop (often abbreviated as REPL). It repeatedly reads an expression typed by the user (in the form of a list), interprets the expression, and displays the resulting value. This form of interpreter is also used by Ruby and Python. Expressions are interpreted by the function EVAL. Literals evaluate to

themselves. So, if you type a number to the interpreter, it simply displays the number. Expressions that are calls to primitive functions are evaluated in the following way: First, each of the parameter expressions is evaluated, in no particular order. Then, the primitive function is applied to the parameter values, and the resulting value is displayed.

Of course, Scheme programs that are stored in files can be loaded and interpreted.

Comments in Scheme are any text following a semicolon on any line.

15.5.3 Primitive Numeric Functions

Scheme includes primitive functions for the basic arithmetic operations. These are `+`, `-`, `*`, and `/`, for add, subtract, multiply, and divide. `*` and `+` can have zero or more parameters. If `*` is given no parameters, it returns `1`; if `+` is given no parameters, it returns `0`. `+` adds all of its parameters together. `*` multiplies all its parameters together. `/` and `-` can have two or more parameters. In the case of subtraction, all but the first parameter are subtracted from the first. Division is similar to subtraction. Some examples are:

Expression	*Value*
`42`	`42`
`(* 3 7)`	`21`
`(+ 5 7 8)`	`20`
`(- 5 6)`	`-1`
`(- 15 7 2)`	`6`
`(- 24 (* 4 3))`	`12`

There are a large number of other numeric functions in Scheme, among them `MODULO`, `ROUND`, `MAX`, `MIN`, `LOG`, `SIN`, and `SQRT`. `SQRT` returns the square root of its numeric parameter, if the parameter's value is not negative. If the parameter is negative, `SQRT` yields a complex number.

In Scheme, note that we use uppercase letters for all reserved words and predefined functions. The official definition of the language specifies that there is no distinction between uppercase and lowercase in these. However, some implementations, for example DrRacket's teaching languages, require lowercase for reserved words and predefined functions.

If a function has a fixed number of parameters, such as `SQRT`, the number of parameters in the call must match that number. If not, the interpreter will produce an error message.

15.5.4 Defining Functions

A Scheme program is a collection of function definitions. Consequently, knowing how to define these functions is a prerequisite to writing the

simplest program. In Scheme, a nameless function actually includes the word LAMBDA, and is called a **lambda expression**. For example,

```
(LAMBDA (x) (* x x))
```

is a nameless function that returns the square of its given numeric parameter. This function can be applied in the same way that named functions are: by placing it in the beginning of a list that contains the actual parameters. For example, the following expression yields 49:

```
((LAMBDA (x) (* x x)) 7)
```

In this expression, x is called a **bound variable** within the lambda expression. During the evaluation of this expression, x is bound to 7. A bound variable never changes in the expression after being bound to an actual parameter value at the time evaluation of the lambda expression begins.

Lambda expressions can have any number of parameters. For example, we could have the following:

```
(LAMBDA (a b c x) (+ (* a x x) (* b x) c))
```

The Scheme special form function DEFINE serves two fundamental needs of Scheme programming: to bind a name to a value and to bind a name to a lambda expression. The form of DEFINE that binds a name to a value may make it appear that DEFINE can be used to create imperative language-style variables. However, these name bindings create named values, not variables.

DEFINE is called a special form because it is interpreted (by EVAL) in a different way than the normal primitives like the arithmetic functions, as we shall soon see.

The simplest form of DEFINE is one used to bind a name to the value of an expression. This form is

(DEFINE symbol expression)

For example,

```
(DEFINE pi 3.14159)
```

```
(DEFINE two_pi (* 2 pi))
```

If these two expressions have been typed to the Scheme interpreter and then `pi` is typed, the number `3.14159` will be displayed; when `two_pi` is typed, `6.28318` will be displayed. In both cases, the displayed numbers may have more digits than are shown here.

This form of `DEFINE` is analogous to a declaration of a named constant in an imperative language. For example, in Java, the equivalents to the above defined names are as follows:

```
final float PI = 3.14159;
final float TWO_PI = 2.0 * PI;
```

Names in Scheme can consist of letters, digits, and special characters except parentheses; they are case insensitive and must not begin with a digit.

The second use of the `DEFINE` function is to bind a lambda expression to a name. In this case, the lambda expression is abbreviated by removing the word `LAMBDA`. To bind a name to a lambda expression, `DEFINE` takes two lists as parameters. The first parameter is the prototype of a function call, with the function name followed by the formal parameters, together in a list. The second list contains an expression to which the name is to be bound. The general form of such a `DEFINE` is3

3. Actually, the general form of `DEFINE` has as its body a list containing a sequence of one or more expressions, although in most cases only one is included. We include only one for simplicity's sake.

```
(DEFINE (function_name parameters)

(expression)

)
```

Of course, this form of `DEFINE` is the definition of a named function.

The following example call to `DEFINE` binds the name `square` to a functional expression that takes one parameter:

```
(DEFINE (square number) (* number number))
```

After the interpreter evaluates this function, it can be used, as in

```
(square 5)
```

which displays `25`.

To illustrate the difference between primitive functions and the `DEFINE` special form, consider the following:

```
(DEFINE x 10)
```

If `DEFINE` were a primitive function, `EVAL`'s first action on this expression would be to evaluate the two parameters of `DEFINE`. If `x` were not already bound to a value, this would be an error. Furthermore, if `x` were already defined, it would also be an error, because this `DEFINE` would attempt to redefine `x`, which is illegal. Remember, `x` is the name of a value; it is not a variable in the imperative sense.

Following is another example of a function. It computes the length of the hypotenuse (the longest side) of a right triangle, given the lengths of the two other sides.

```
(DEFINE (hypotenuse side1 side2)
    (SQRT(+(square side1)(square side2)))
)
```

Notice that `hypotenuse` uses `square`, which was defined previously.

15.5.5 Output Functions

Scheme includes a few simple output functions, but when used with the interactive interpreter, most output from Scheme programs is the normal output from the interpreter, displaying the results of applying `EVAL` to top-level functions.

Note that explicit input and output are not part of the pure functional

programming model, because input operations change the program state and output operations have side effects. Neither of these can be part of a pure functional language. Therefore, this chapter does not describe the explicit input or output functions of Scheme.

15.5.6 Numeric Predicate Functions

A predicate function is one that returns a Boolean value (some representation of either true or false). Scheme includes a collection of predicate functions for numeric data. Among them are the following:

Function	*Meaning*
=	Equal
<>	Not equal
>	Greater than
<	Less than
>=	Greater than or equal to
<=	Less than or equal to
EVEN?	Is it an even number?
ODD?	Is it an odd number?
ZERO?	Is it zero?

Notice that the names for all predefined predicate functions that have words for names end with question marks. In Scheme, the two Boolean values are

#T and #F (or #t and #f), although the Scheme predefined predicate functions return the empty list, (), for false.

When a list is interpreted as a Boolean, any nonempty list evaluates to true; the empty list evaluates to false. This is similar to the interpretation of integers in C as Boolean values; zero evaluates to false and any nonzero value evaluates to true.

In the interest of readability, all of our example predicate functions in this chapter return #F, rather than ().

The NOT function is used to invert the logic of a Boolean expression.

15.5.7 Control Flow

Scheme uses three different constructs for control flow: one similar to the selection construct of the imperative languages and two based on the evaluation control used in mathematical functions.

The Scheme two-way selector function, named IF, has three parameters: a predicate expression, a then expression, and an else expression. A call to IF has the form

(IF predicate then_expression else_expression)

For example,

```
(DEFINE (factorial n)
  (IF (<= n 1)
    1
    (* n (factorial (- n 1)))
))
```

Recall that the multiple selection of Scheme, COND, was discussed in Chapter 8. Following is an example of a simple function that uses COND:

```
(DEFINE (leap? year)
  (COND
    ((ZERO? (MODULO year 400)) #T)
```

```
    ((ZERO? (MODULO year 100)) #F)
    (ELSE (ZERO? (MODULO year 4)))
))
```

The following subsections contain additional examples of the use of COND.

The third Scheme control mechanism is recursion, which is used, as in mathematics, to specify repetition. Most of the example functions in Section 15.5.10 use recursion.

15.5.8 List Functions

One of the more common uses of the Lisp-based programming languages is list processing. This subsection introduces the Scheme functions for dealing with lists. Recall that Scheme's list operations were briefly introduced in Chapter 6. Following is a more detailed discussion of list processing in Scheme.

Scheme programs are interpreted by the function application function, EVAL. When applied to a primitive function, EVAL first evaluates the parameters of the given function. This action is necessary when the actual parameters in a function call are themselves function calls, which is frequently the case. In some calls, however, the parameters are data elements rather than function references. When a parameter is not a function reference, it obviously should not be evaluated. We were not concerned with this earlier, because numeric literals always evaluate to themselves and cannot be mistaken for function names.

Suppose we have a function that has two parameters, an atom and a list, and the purpose of the function is to determine whether the given atom is in the given list. Neither the atom nor the list should be evaluated; they are literal data to be processed. To avoid evaluating a parameter, it is first given as a parameter to the primitive function QUOTE, which simply returns it without change. The following examples illustrate QUOTE:

```
(QUOTE A) returns A
(QUOTE (A B C)) returns (A B C)
```

Calls to QUOTE are usually abbreviated by preceding the expression to be quoted with an apostrophe (') and leaving out the parentheses around the expression. Thus, instead of (QUOTE (A B)), '(A B) is used.

The necessity of QUOTE arises because of the fundamental nature of Scheme (and the other Lisp-based languages): data and code have the same form. Although this may seem odd to imperative language programmers, it results in some interesting and powerful processes, one of which is discussed in Section 15.5.14.

The CAR, CDR, and CONS functions were introduced in Chapter 6. Following are additional examples of the operations of CAR and CDR:

```
(CAR '(A B C)) returns A
(CAR '((A B) C D)) returns (A B)
(CAR 'A) is an error because A is not a list
(CAR '(A)) returns A
(CAR '()) is an error
(CDR '(A B C)) returns (B C)
(CDR '((A B) C D)) returns (C D)
(CDR 'A) is an error
(CDR '(A)) returns ()
(CDR '()) is an error
```

The names of the CAR and CDR functions are peculiar at best. The origin of these names lies in the first implementation of Lisp, which was on an IBM 704 computer. The 704's memory words had two fields, named *decrement* and *address*, that were used in various operand addressing strategies. Each of these fields could store a machine memory address. The 704 also included two machine instructions, also named CAR (*c*ontents of the *a*ddress part of a *r*egister) and CDR (*c*ontents of the *d*ecrement part of a *r*egister), that extracted the associated fields. It was natural to use the two fields to store the two pointers of a list node so that a memory word could neatly store a node. Using these conventions, the CAR and CDR instructions of the 704 provided efficient list selectors. The names carried over into the primitives of all dialects of Lisp.

As another example of a simple function, consider

```
(DEFINE (second a_list) (CAR (CDR a_list)))
```

Once this function is evaluated, it can be used, as in

```
(second '(A B C))
```

which returns B.

Some of the most commonly used functional compositions in Scheme are built in as single functions. For example, (CAAR x) is equivalent to (CAR(CAR x)), (CADR x) is equivalent to (CAR (CDR x)), and (CADDAR x) is equivalent to (CAR (CDR (CDR (CAR x)))). Any combination of A's and D's, up to four, are legal between the 'C' and the 'R' in the function's name. As an example, consider the following evaluation of CADDAR:

```
(CADDAR '((A B (C) D) E)) =
(CAR (CDR (CDR (CAR '((A B (C) D) E))))) =
(CAR (CDR (CDR '(A B (C) D)))) =
(CAR (CDR '(B (C) D))) =
(CAR '((C) D)) =
(C)
```

Following are example calls to CONS:

```
(CONS 'A '()) returns (A)
(CONS 'A '(B C)) returns (A B C)
(CONS '() '(A B)) returns (() A B)
(CONS '(A B) '(C D)) returns ((A B) C D)
```

The results of these CONS operations are shown in Figure 15.2. Note that CONS is, in a sense, the inverse of CAR and CDR. CAR and CDR take a list apart, and CONS constructs a new list from two given list parts. The two parameters to CONS become the CAR and CDR of the new list. Thus, if a_list is a list, then

```
(CONS (CAR a_list) (CDR a_list))
```

returns a list with the same structure and same elements as a_list.

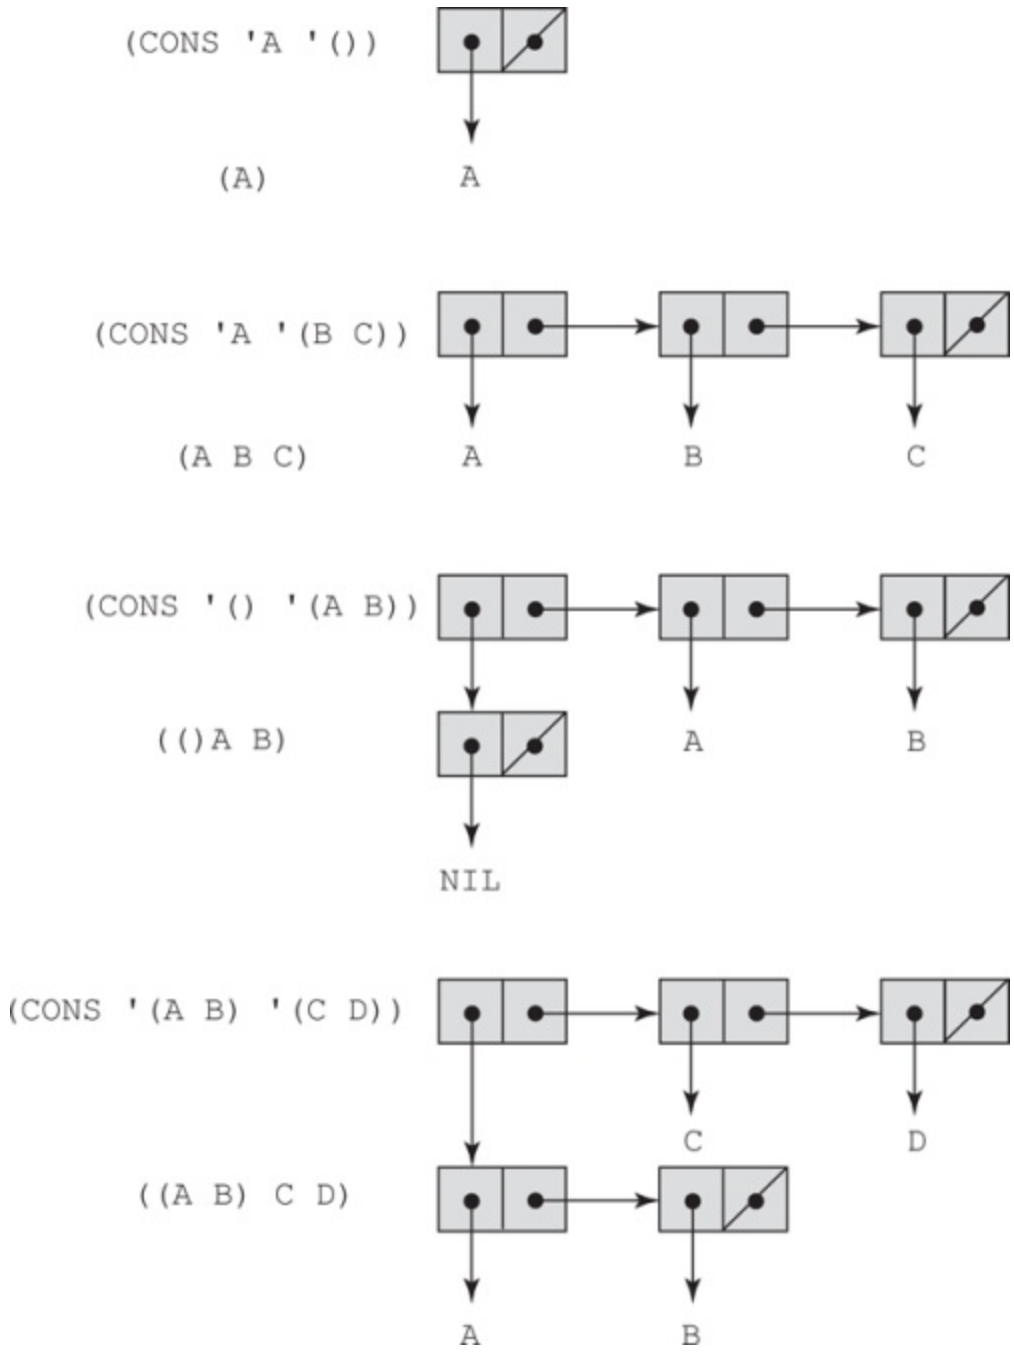

Figure 15.2 The result of several CONS operations

Figure 15.2 Full Alternative Text

Dealing only with the relatively simple problems and programs discussed in this chapter, it is unlikely one would intentionally apply CONS to two atoms, although that is legal. The result of such an application is a dotted pair, so named because of the way it is displayed by Scheme. For example, consider the following call:

```
(CONS 'A 'B)
```

If the result of this is displayed, it would appear as

```
(A . B)
```

This dotted pair indicates that instead of an atom and a pointer or a pointer and a pointer, this cell has two atoms.

LIST is a function that constructs a list from a variable number of parameters. It is a shorthand version of nested CONS functions, as illustrated in the following:

```
(LIST 'apple 'orange 'grape)
```

returns

```
(apple orange grape)
```

Using CONS, the call to LIST above is written as follows:

```
(CONS 'apple (CONS 'orange (CONS 'grape '())))
```

15.5.9 Predicate Functions for Symbolic Atoms and Lists

Scheme has three fundamental predicate functions, EQ?, NULL?, and LIST?, for symbolic atoms and lists.

The EQ? function takes two expressions as parameters, although it is usually used with two symbolic atom parameters. It returns #T if both parameters

have the same pointer value—that is, they point to the same atom or list; otherwise, it returns #F. If the two parameters are symbolic atoms, EQ? returns #T if they are the same symbols (because Scheme does not make duplicates of symbols); otherwise #F. Consider the following examples:

```
(EQ? 'A 'A) returns #T
(EQ? 'A 'B) returns #F
(EQ? 'A '(A B)) returns #F
(EQ? '(A B) '(A B)) returns #F or #T
(EQ? 3.4 (+ 3 0.4)) returns #F or #T
```

As the fourth example indicates, the result of comparing lists with EQ? is not consistent. The reason for this is that two lists that are exactly the same often are not duplicated in memory. At the time the Scheme system creates a list, it checks to see whether there is already such a list. If there is, the new list is nothing more than a pointer to the existing list. In these cases, the two lists will be judged equal by EQ?. However, in some cases, it may be difficult to detect the presence of an identical list, in which case a new list is created. In this scenario, EQ? yields #F.

The last case shows that the addition may produce a new value, in which case it would not be equal (with EQ?) to 3.4, or it may recognize that it already has the value 3.4 and use it, in which case EQ? will use the pointer to the old 3.4 and return #T.

As we have seen, EQ? works for symbolic atoms but does not necessarily work for numeric atoms. The = predicate works for numeric atoms but not symbolic atoms. As discussed previously, EQ? also does not work reliably for list parameters.

Sometimes it is convenient to be able to test two atoms for equality when it is not known whether they are symbolic or numeric. For this purpose, Scheme has a different predicate, EQV?, which works on both numeric and symbolic atoms. Consider the following examples:

```
(EQV? 'A 'A) returns #T
(EQV? 'A 'B) returns #F
(EQV? 3 3) returns #T
(EQV? 'A 3) returns #F
(EQV? 3.4 (+ 3 0.4)) returns #T
```

```
(EQV? 3.0 3) returns #F
```

Notice that the last example demonstrates that floating-point values are different from integer values. `EQV?` is not a pointer comparison, it is a value comparison.

The primary reason to use `EQ?` or `=` rather than `EQV?` when it is possible is that `EQ?` and `=` are faster than `EQV?`.

The `LIST?` predicate function returns `#T` if its single argument is a list and `#F` otherwise, as in the following examples:

```
(LIST? '(X Y)) returns #T
(LIST? 'X) returns #F
(LIST? '()) returns #T
```

The `NULL?` function tests its parameter to determine whether it is the empty list and returns `#T` if it is. Consider the following examples:

```
 (NULL? '(A B)) returns #F
(NULL? '()) returns #T
(NULL? 'A) returns #F
(NULL? '(())) returns #F
```

The last call yields `#F` because the parameter is not the empty list. Rather, it is a list containing a single element, the empty list.

15.5.10 Example Scheme Functions

This section contains several examples of function definitions in Scheme. These programs solve simple list-processing problems.

Consider the problem of membership of a given atom in a given list that does not include sublists. Such a list is called a **simple list**. If the function is named `member`, it could be used as follows:

```
(member 'B '(A B C)) returns #T
```

```
(member 'B '(A C D E)) returns #F
```

Thinking in terms of iteration, the membership problem is simply to compare the given atom and the individual elements of the given list, one at a time in some order, until either a match is found or there are no more elements in the list to be compared. A similar process can be accomplished using recursion. The function can compare the given atom with the CAR of the list. If they match, the value #T is returned. If they do not match, the CAR of the list should be ignored and the search continued on the CDR of the list. This can be done by having the function call itself with the CDR of the list as the list parameter and return the result of this recursive call. This process will end if the given atom is found in the list. If the atom is not in the list, the function will eventually be called (by itself) with a null list as the actual parameter. That event must force the function to return #F. In this process, there are two ways out of the recursion: Either the list is empty on some call, in which case #F is returned, or a match is found and #T is returned.

Altogether, there are three cases that must be handled in the function: an empty input list, a match between the atom and the CAR of the list, or a mismatch between the atom and the CAR of the list, which causes the recursive call. These three are the three parameters to COND, with the last being the default case that is triggered by an ELSE predicate. The complete function follows:4

4. Most Scheme systems define a function named member and do not allow a user to redefine it. So, if the reader wants to try this function, it must be defined with some other name.

```
(DEFINE (member atm a_list)
  (COND
    ((NULL? a_list) #F)
    ((EQ? atm (CAR a_list)) #T)
    (ELSE (member atm (CDR a_list)))
))
```

This form is typical of simple Scheme list-processing functions. In such functions, the data in lists are processed one element at a time. The individual elements are specified with CAR, and the process is continued using recursion on the CDR of the list.

Note that the null test must precede the equal test, because applying CAR to an empty list is an error.

As another example, consider the problem of determining whether two given lists are equal. If the two lists are simple, the solution is relatively easy, although some programming techniques with which the reader may not be familiar are involved. A predicate function, equalsimp, for comparing simple lists is shown here:

```
(DEFINE (equalsimp list1 list2)
  (COND
    ((NULL? list1) (NULL? list2))
    ((NULL? list2) #F)
    ((EQ? (CAR list1) (CAR list2))
          (equalsimp (CDR list1) (CDR list2)))
    (ELSE #F)
))
```

The first case, which is handled by the first parameter to COND, is for when the first list parameter is the empty list. This can occur in an external call if the first list parameter is initially empty. Because a recursive call uses the CDRs of the two parameter lists as its parameters, the first list parameter can be empty in such a call (if the first list parameter is now empty). When the first list parameter is empty, the second list parameter must be checked to see whether it is also empty. If so, they are equal (either initially or the CARs were equal on all previous recursive calls), and NULL? correctly returns #T. If the second list parameter is not empty, it is larger than the first list parameter and #F should be returned, as it is by NULL?.

The next case deals with the second list being empty when the first list is not. This situation occurs only when the first list is longer than the second. Only the second list must be tested, because the first case catches all instances of the first list being empty.

The third case is the recursive step that tests for equality between two corresponding elements in the two lists. It does this by comparing the CARs of the two nonempty lists. If they are equal, then the two lists are equal up to that point, so recursion is used on the CDRs of both. This case fails when two unequal atoms are found. When this occurs, the process need not continue, so

the default case ELSE is selected, which returns #F.

Note that equalsimp expects lists as parameters and does not operate correctly if either or both parameters are atoms.

The problem of comparing general lists is slightly more complex than this, because sublists must be traced completely in the comparison process. In this situation, the power of recursion is uniquely appropriate, because the form of sublists is the same as that of the given lists. Any time the corresponding elements of the two given lists are lists, they are separated into their two parts, CAR and CDR, and recursion is used on them. This is a perfect example of the usefulness of the divide-and-conquer approach. If the corresponding elements of the two given lists are atoms, they can simply be compared using EQ?.

The definition of the complete function follows:

```
(DEFINE (equal list1 list2)
  (COND
    ((NOT (LIST? list1)) (EQ? list1 list2))
    ((NOT (LIST? list2)) #F)
    ((NULL? list1) (NULL? list2))
    ((NULL? list2) #F)
    ((equal (CAR list1) (CAR list2))
            (equal (CDR list1) (CDR list2)))
    (ELSE #F)
))
```

The first two cases of the COND handle the situation where either of the parameters is an atom instead of a list. The third and fourth cases are for the situation where one or both lists are empty. These cases also prevent subsequent cases from attempting to apply CAR to an empty list. The fifth COND case is the most interesting. The predicate is a recursive call with the CARs of the lists as parameters. If this recursive call returns #T, then recursion is used again on the CDRs of the lists. This algorithm allows the two lists to include sublists to any depth.

This definition of equal works on any pair of expressions, not just lists. equal is equivalent to the system predicate function EQUAL?. Note that EQUAL? should be used only when necessary (the forms of the actual parameters are

not known), because it is much slower than EQ? and EQV?.

Another commonly needed list operation is that of constructing a new list that contains all of the elements of two given list arguments. This is usually implemented as a Scheme function named append. The result list can be constructed by repeated use of CONS to place the elements of the first list argument into the second list argument, which becomes the result list. To clarify the action of append, consider the following examples:

```
(append '(A B) '(C D R)) returns (A B C D R)
(append '((A B) C) '(D (E F))) returns ((A B) C D (E F))
```

The definition of append is[5]

5. As was the case with member, a user usually cannot define a function named append.

```
(DEFINE (append list1 list2)
  (COND
    ((NULL? list1) list2)
    (ELSE (CONS (CAR list1) (append (CDR list1) list2)))
))
```

The first COND case is used to terminate the recursive process when the first argument list is empty, returning the second list. In the second case (the ELSE), the CAR of the first parameter list is CONSed onto the result returned by the recursive call, which passes the CDR of the first list as its first parameter.

Consider the following Scheme function, named guess, which uses the member function described in this section. Try to determine what it does before reading the description that follows it. Assume the parameters are simple lists.

```
(DEFINE (guess list1 list2)
  (COND
    ((NULL? list1) '())
    ((member (CAR list1) list2)
             (CONS (CAR list1) (guess (CDR list1) list2)))
    (ELSE (guess (CDR list1) list2))
))
```

guess yields a simple list that contains the common elements of its two parameter lists. So, if the parameter lists represent sets, guess computes a list that represents the intersection of those two sets.

15.5.11 LET

LET is a function (initially described in Chapter 5) that creates a local scope in which names are temporarily bound to the values of expressions. It is often used to factor out the common subexpressions from more complicated expressions. These names can then be used in the evaluation of another expression, but they cannot be rebound to new values in LET. The following example illustrates the use of LET. It computes the roots of a given quadratic equation, assuming the roots are real.6 The mathematical definitions of the real (as opposed to complex) roots of the quadratic equation ax2+bx+c are as follows: root1=(−b+sqrt(b2−4 ac))/2a and root 2=(−b−sqrt(b2−4 ac))/2 a

6. Some versions of Scheme include “complex” as a data type and will compute the roots of the equation, regardless of whether they are real or complex.

```
(DEFINE (quadratic_roots a b c)
  (LET (
    (root_part_over_2a
                (/ (SQRT (- (* b b) (* 4 a c))) (* 2 a)))
    (minus_b_over_2a (/ (- 0 b) (* 2 a)))
        )
  (LIST (+ minus_b_over_2a root_part_over_2a)
             (- minus_b_over_2a root_part_over_2a))
))
```

This example uses LIST to create the list of the two values that make up the result.

Because the names bound in the first part of a LET construct cannot be changed in the following expression, they are not the same as local variables in a block in an imperative language. They could all be eliminated by textual substitution of their respective expressions for their names in the LET expression.

LET is actually shorthand for a LAMBDA expression applied to a parameter. The following two expressions are equivalent:

```
(LET ((alpha 7))(* 5 alpha))
((LAMBDA (alpha) (* 5 alpha)) 7)
```

In the first expression, 7 is bound to alpha with LET; in the second, 7 is bound to alpha through the parameter of the LAMBDA expression.

15.5.12 Tail Recursion in Scheme

A function is **tail recursive** if its recursive call is the last operation in the function. This means that the return value of the recursive call is the return value of the nonrecursive call to the function. For example, the member function of Section 15.5.10, repeated here, is tail recursive.

```
(DEFINE (member atm a_list)
  (COND
    ((NULL? a_list) #F)
    ((EQ? atm (CAR a_list)) #T)
    (ELSE (member atm (CDR a_list)))
))
```

This function can be automatically converted by a compiler to use iteration, resulting in faster execution than in its recursive form.

However, many functions that use recursion for repetition are not tail recursive. Programmers who are concerned with efficiency have discovered ways to rewrite some of these functions so that they are tail recursive. One example of this uses an accumulating parameter and a helper function. As an example of this approach, consider the factorial function from Section 15.5.7, which is repeated here:

```
(DEFINE (factorial n)
  (IF (<= n 1)
    1
    (* n (factorial (- n 1)))
))
```

The last operation of this function is the multiplication. The function works by creating the list of numbers to be multiplied together and then doing the multiplications as the recursion unwinds to produce the result. Each of these numbers is created by an activation of the function and each is stored in an activation record instance. As the recursion unwinds the numbers are multiplied together. Recall that the stack is shown after several recursive calls to factorial in Chapter 9. This factorial function can be rewritten with an auxiliary helper function, which uses a parameter to accumulate the partial factorial. The helper function, which is tail recursive, also takes `factorial`'s parameter. These functions are as follows:

```
(DEFINE (facthelper n factpartial)
  (IF (<= n 1)
    factpartial
    (facthelper (- n 1) (* n factpartial))
))
(DEFINE (factorial n)
  (facthelper n 1)
)
```

With these functions, the result is computed during the recursive calls, rather than as the recursion unwinds. Because there is nothing useful in the activation record instances, they are not necessary. Regardless of how many recursive calls are requested, only one activation record instance is necessary. This makes the tail-recursive version far more efficient than the non-tail-recursive version.

The Scheme language definition requires that Scheme language processing systems convert all tail-recursive functions to replace that recursion with iteration. Therefore, it is important, at least for efficiency's sake, to define functions that use recursion to specify repetition to be tail recursive. Some optimizing compilers for some functional languages can even perform conversions of some non-tail-recursive functions to equivalent tail-recursive functions and then code these functions to use iteration instead of recursion for repetition.

15.5.13 Functional Forms

This section describes two common mathematical functional forms that are provided by Scheme: composition and apply-to-all. Both are mathematically defined in Section 15.2.2.

15.5.13.1 Functional Composition

Functional composition is the only primitive functional form provided by the original Lisp. All subsequent Lisp dialects, including Scheme, also provide it. As stated in Section 15.2.2, function composition is a functional form that takes two functions as parameters and returns a function that first applies the second parameter function to its parameter and then applies the first parameter function to the return value of the second parameter function. In other words, the function `h` is the composition function of `f` and `g` if `h(x) = f(g(x))`. For example, consider the following example:

```
(DEFINE (g x) (* 3 x))
(DEFINE (f x) (+ 2 x))
```

Now the functional composition of `f` and `g` can be written as follows:

```
(DEFINE (h x) (+ 2 (* 3 x)))
```

In Scheme, the functional composition function `compose` can be written as follows:

```
(DEFINE (compose f g) (LAMBDA (x)(f (g x))))
```

For example, we could have the following:

```
((compose CAR CDR) '((a b) c d))
```

This call would yield `c`. This is an alternative, though less efficient, form of `CADR`. Now consider another call to `compose`:

```
((compose CDR CAR) '((a b) c d))
```

This call would yield `(b)`. This is an alternative to `CDAR`.

As yet another example of the use of compose, consider the following:

```
(DEFINE (third a_list)
 ((compose CAR (compose CDR CDR)) a_list))
```

This is an alternative to CADDR.

15.5.13.2 An Apply-to-All Functional Form

The most common functional forms provided in functional programming languages are variations of mathematical apply-to-all functional forms. The simplest of these is map, which has two parameters: a function and a list. map applies the given function to each element of the given list and returns a list of the results of these applications. A Scheme definition of map follows:7

7. As was the case with member, map is a predefined function that cannot be redefined by users.

```
(DEFINE (map fun a_list)
  (COND
    ((NULL? a_list) '())
    (ELSE (CONS (fun (CAR a_list)) (map fun (CDR a_list))))
))
```

Note the simple form of map, which expresses a complex functional form.

As an example of the use of map, suppose we want all of the elements of a list cubed. We can accomplish this with the following:

```
(map (LAMBDA (num) (* num num num)) '(3 4 2 6))
```

This call returns (27 64 8 216).

Note that in this example, the first parameter to mapcar is a LAMBDA expression. When EVAL evaluates the LAMBDA expression, it constructs a function that has the same form as any predefined function except that it is

nameless. In the example expression, this nameless function is immediately applied to each element of the parameter list and the results are returned in a list.

15.5.14 Functions That Build Code

The fact that programs and data have the same structure can be exploited in constructing programs. Recall that the Scheme interpreter uses a function named EVAL. The Scheme system applies EVAL to every expression typed, whether it is at the Scheme prompt in the interactive interpreter or is part of a program being interpreted. The EVAL function can also be called directly by Scheme programs. This provides the possibility of a Scheme program creating expressions and calling EVAL to evaluate them. This is not something that is unique to Scheme, but the simple forms of its expressions make it easy to create them during execution.

One of the simplest examples of this process involves numeric atoms. Recall that Scheme includes a function named +, which takes any number of numeric atoms as arguments and returns their sum. For example, `(+ 3 7 10 2)` returns `22`.

Our problem is the following: Suppose that in a program we have a list of numeric atoms and need the sum. We cannot apply + directly on the list, because + can take only atomic parameters, not a list of numeric atoms. We could, of course, write a function that repeatedly adds the CAR of the list to the sum of its CDR, using recursion to go through the list. Such a function follows:

```
(DEFINE (adder a_list)
  (COND
    ((NULL? a_list) 0)
    (ELSE (+ (CAR a_list) (adder (CDR a_list))))
))
```

Following is an example call to `adder`, along with the recursive calls and returns:

```
(adder '(3 4 5))
(+ 3 (adder (4 5)))
```

```
(+ 3 (+ 4 (adder (5))))
(+ 3 (+ 4 (+ 5 (adder ()))))
(+ 3 (+ 4 (+ 5 0)))
(+ 3 (+ 4 5))
(+ 3 9)
(12)
```

An alternative solution to the problem is to write a function that builds a call to + with the proper parameter forms. This can be done by using CONS to build a new list that is identical to the parameter list except it has the atom + inserted at its beginning. This new list can then be submitted to EVAL for evaluation, as in the following:

```
(DEFINE (adder a_list)
  (COND
    ((NULL? a_list) 0)
    (ELSE (EVAL (CONS '+ a_list)))
))
```

Note that the + function's name is quoted to prevent EVAL from evaluating it in the evaluation of CONS. Following is an example call to this new version of adder, along with the call to EVAL and the return value:

```
(adder '(3 4 5))
(EVAL (+ 3 4 5)
(12)
```

In all earlier versions of Scheme, the EVAL function evaluated its expression in the outermost scope of the program. The later versions of Scheme, beginning with Scheme 4, requires a second parameter to EVAL that specifies the scope in which the expression is to be evaluated. For simplicity's sake, we left the scope parameter out of our example, and we do not discuss scope names here.

15.6 Common Lisp

Common Lisp (Steele, 1990) was created in an effort to combine the features of several early 1980s dialects of Lisp, including Scheme, into a single language. Being something of a union of languages, it is quite large and complex, similar in these regards to C++ and C#. Its basis, however, is the original Lisp, so its syntax, primitive functions, and fundamental nature come from that language.

Following is the factorial function written in Common Lisp:

```
(DEFUN factorial (x)
  (IF (<= n 1)
    1
    (* n factorial (- n 1)))
))
```

Only the first line of this function differs syntactically from the Scheme version of the same function.

The list of features of Common Lisp is long: a large number of data types and structures, including records, arrays, complex numbers, and character strings; powerful input and output operations; and a form of packages for modularizing collections of functions and data, and also for providing access control. Common Lisp includes several imperative constructs, as well as some mutable types.

Recognizing the occasional flexibility provided by dynamic scoping, as well as the simplicity of static scoping, Common Lisp allows both. The default scoping for variables is static, but by declaring a variable to be “special,” that variable becomes dynamically scoped.

Macros are often used in Common Lisp to extend the language. In fact, some of the predefined functions are actually macros. For example, `DOLIST`, which takes two parameters, a variable and a list, is a macro. For example, consider the following:

```
(DOLIST (x '(1 2 3)) (print x))
```

This produces the following:

```
1
2
3
NIL
```

`NIL` here is the return value of `DOLIST`.

Macros create their effect in two steps: First, the macro is expanded. Second, the expanded macro, which is Lisp code, is evaluated. Users can define their own macros with `DEFMACRO`.

The Common Lisp backquote operator (`` ` ``) is similar to Scheme's `QUOTE`, except some parts of the parameter can be unquoted by preceding them with commas. For example, consider the following two examples:

```
`(a (* 3 4) c)
```

This expression evaluates to `(a (* 3 4) c)`. However, the following expression:

```
`(a ,(* 3 4) c)
```

evaluates to `(a 12 c)`.

Lisp implementations have a front end called the *reader* that transforms the text of Lisp programs into a code representation. Then, the macro calls in the code representation are expanded into code representations. The output of this step is then either interpreted or compiled into the machine language of the host computer, or perhaps into an intermediate code than can be interpreted. There is a special kind of macro, named *reader macros* or *read macros*, that are expanded during the reader phase of a Lisp language processor. A reader macro expands a specific character into a string of Lisp code. For example, the apostrophe in Lisp is a read macro that expands to a call to `QUOTE`. Users can define their own reader macros to create other shorthand constructs.

Common Lisp, as well as other Lisp-based languages, have a symbol data type. The reserved words are symbols that evaluate to themselves, as are `T` and `NIL`. Technically, symbols are either bound or unbound. Parameter symbols are bound while the function is being evaluated. Also, symbols that are the names of imperative-style variables and have been assigned values are bound. Other symbols are unbound. For example, consider the following expression:

```
(LIST '(A B C))
```

The symbols `A`, `B`, and `C` are unbound. Recall that Ruby also has a symbol data type.

In a sense, Scheme and Common Lisp are opposites. Scheme is far smaller and semantically simpler, in part because of its exclusive use of static scoping, but also because it was designed to be used for teaching programming, whereas Common Lisp was meant to be a commercial language. Common Lisp has succeeded in being a widely used language for AI applications, among other areas. Scheme, on the other hand, is more frequently used in college courses on functional programming. It is also more likely to be studied as a functional language because of its relatively small size. An important design goal of Common Lisp that caused it to be a large language was the desire to make it compatible with several of the dialects of Lisp from which it was derived.

The Common Lisp Object System (CLOS) (Paepeke, 1993) was developed in the late 1980s as an object-oriented version of Common Lisp. This language supports generic functions and multiple inheritance, among other constructs.

15.7 ML

ML (Milner et al., 1997) is a static-scoped functional programming language, like Scheme. However, it differs from Lisp and its dialects, including Scheme, in a number of significant ways. One important difference is that ML is a strongly typed language, whereas Scheme is essentially typeless. ML has type declarations for function parameters and the return types of functions, although because of its type inferencing they are often not used. The type of every variable and expression can be statically determined. ML, like other functional programming languages, does not have variables in the sense of the imperative languages. It does have identifiers, which have the appearance of names of variables in imperative languages. However, these identifiers are best thought of as names for values. Once set, they cannot be changed. They are like the named constants of imperative languages like **`final`** declarations in Java. ML identifiers do not have fixed types—any identifier can be the name of a value of any type.

A table called the **evaluation environment** stores the names of all implicitly and explicitly declared identifiers in a program, along with their types. This is like a run-time symbol table. When an identifier is declared, either implicitly or explicitly, it is placed in the evaluation environment.

Another important difference between Scheme and ML is that ML uses a syntax that is more closely related to that of an imperative language than that of Lisp. For example, arithmetic expressions are written in ML using infix notation.

Function declarations in ML appear in the general form

```
fun function_name(formal parameters) = expression;
```

When called, the value of the expression is returned by the function. Actually, the expression can be a list of expressions, separated by semicolons and surrounded by parentheses. The return value in this case is that of the last expression. Of course, unless they have side effects, the expressions before the last serve no purpose. Because we are not considering the parts of ML

that have side effects, we only consider function definitions with a single expression.

Now we can discuss type inference. Consider the following ML function declaration:

```
fun circumf(r) = 3.14159 * r * r;
```

This specifies a function named `circumf` that takes a floating-point (**real** in ML) parameter and produces a floating-point result. The types are inferred from the type of the literal in the expression. Likewise, in the function

```
fun times10(x) = 10 * x;
```

the parameter and functional value are inferred to be of type **int**.

Consider the following ML function:

```
fun square(x) = x * x;
```

ML determines the type of both the parameter and the return value from the * operator in the function definition. Because this is an arithmetic operator, the type of the parameter and the function are assumed to be numeric. In ML, the default numeric type is **int**. So, it is inferred that the type of the parameter and the return value of `square` is **int**.

If `square` were called with a floating-point value, as in

```
square(2.75);
```

it would cause an error, because ML does not coerce **real** values to **int** type. If we wanted `square` to accept **real** parameters, it could be rewritten as

```
fun square(x) : real = x * x;
```

Because ML does not allow overloaded functions, this version could not coexist with the earlier **int** version. The last version defined would be the only one.

The fact that the functional value is typed **real** is sufficient to infer that the

parameter is also **real** type. Each of the following definitions is also legal:

```
fun square(x : real) = x * x;
fun square(x) = (x : real) * x;
fun square(x) = x * (x : real);
```

Type inference is also used in the functional languages Miranda, Haskell, and F#.

The ML selection control flow construct is similar to that of the imperative languages. It has the following general form:

```
if expression then then_expression else else_expression
```

The first expression must evaluate to a Boolean value.

The conditional expressions of Scheme can appear at the function definition level in ML. In Scheme, the `COND` function is used to determine the value of the given parameter, which in turn specifies the value returned by `COND`. In ML, the computation performed by a function can be defined for different forms of the given parameter. This feature is meant to mimic the form and meaning of conditional function definitions in mathematics. In ML, the particular expression that defines the return value of a function is chosen by pattern matching against the given parameter. For example, without using this pattern matching, a function to compute factorial could be written as follows:

```
fun fact(n : int): int = if n <= 1 then 1
                         else n * fact(n - 1);
```

Multiple definitions of a function can be written using parameter pattern matching. The different function definitions that depend on the form of the parameter are separated by an OR symbol (`|`). For example, using pattern matching, the factorial function could be written as follows:

```
fun fact(0) = 1
|   fact(1) = 1
|  fact(n : int): int = n * fact(n - 1);
```

If `fact` is called with the actual parameter `0`, the first definition is used; if the

actual parameter is 1, the second definition is used; if an **`int`** value that is neither `0` nor `1` is sent, the third definition is used.

As discussed in Chapter 6, ML supports lists and list operations. Recall that `hd`, `tl`, and `::` are ML's versions of Scheme's `CAR`, `CDR`, and `CONS`.

Because of the availability of patterned function parameters, the `hd` and `tl` functions are much less frequently used in ML than `CAR` and `CDR` are used in Scheme. For example, in a formal parameter, the expression

```
(h :: t)
```

is actually two formal parameters, the head and tail of given list parameter, while the single corresponding actual parameter is a list. For example, the number of elements in a given list can be computed with the following function:

```
fun length([]) = 0
|   length(h :: t) = 1 + length(t);
```

As another example of these concepts, consider the `append` function, which does what the Scheme `append` function does:

```
fun append([], lis2) = lis2
|   append(h :: t, lis2) = h :: append(t, lis2);
```

The first case in this function handles the situation of the function being called with an empty list as the first parameter. This case also terminates the recursion when the initial call has a nonempty first parameter. The second case of the function breaks the first parameter list into its head and tail (`hd` and `tl`). The head is `CONS`ed onto the result of the recursive call, which uses the tail as its first parameter.

In ML, names are bound to values with value declaration statements of the form

```
val new_name = expression;
```

For example,

```
val distance = time * speed;
```

Do not get the idea that this statement is exactly like the assignment statements in the imperative languages, for it is not. The **val** statement binds a name to a value, but the name cannot be later rebound to a new value. Well, in a sense it can. Actually, if you do rebind a name with a second **val** statement, it causes a new entry in the evaluation environment that is not related to the previous version of the name. In fact, after the new binding, the old evaluation environment entry (for the previous binding) is no longer visible. Also, the type of the new binding need not be the same as that of the previous binding. **val** statements do not have side effects. They simply add a name to the current evaluation environment and bind it to a value.

The normal use of **val** is in a **let** expression.8 Consider the following example:

8. Let expressions in ML were introduced in Chapter 5.

```
let val radius = 2.7
    val pi = 3.14159
in pi * radius * radius
end;
```

ML includes several higher-order functions that are commonly used in functional programming. Among these are a filtering function for lists, `filter`, which takes a predicate function as its parameter. The predicate function is often given as a lambda expression, which in ML is defined exactly like a function, except with the **fn** reserved word, instead of **fun**, and of course the lambda expression is nameless. `filter` returns a function that takes a list as a parameter. It tests each element of the list with the predicate. Each element on which the predicate returns true is added to a new list, which is the return value of the function. Consider the following use of `filter`:

```
filter(fn(x) => x < 100, [25, 1, 50, 711, 100, 150, 27,
    161, 3]);
```

This application would return `[25, 1, 50, 27, 3]`.

The `map` function takes a single parameter, which is a function. The resulting function takes a list as a parameter. It applies its function to each element of

the list and returns a list of the results of those applications. Consider the following code:

```
fun cube x = x * x * x;
val cubeList = map cube;
val newList = cubeList [1, 3, 5];
```

After execution, the value of `newList` is `[1, 27, 125]`. This could be done more simply by defining the cube function as a lambda expression, as in the following:

```
val newList = map (fn x => x * x * x, [1, 3, 5]);
```

ML has a binary operator for composing two functions, `o` (a lowercase "oh"). For example, to build a function `h` that first applies function `f` and then applies function `g` to the returned value from `f`, we could use the following:

```
val h = g o f;
```

Strictly speaking, ML functions take a single parameter. When a function is defined with more than one parameter, ML considers the parameters to be a tuple, even though the parentheses that normally delimit a tuple value are optional. The commas that separate the parameters (tuple elements) are required.

The process of **currying** replaces a function with more than one parameter with a function with one parameter that returns a function that takes the other parameters of the initial function.

ML functions that take more than one parameter can be defined in curried form by leaving out the commas between the parameters (and the delimiting parentheses).9 For example, we could have the following:

9. This form of functions is named for Haskell Curry, a British mathematician who studied them.

```
fun add a b = a + b;
```

Although this appears to define a function with two parameters, it actually defines one with just one parameter. The `add` function takes an integer

parameter (`a`) and returns a function that also takes an integer parameter (`b`). A call to this function also excludes the commas between the parameters, as in the following:

```
add 3 5;
```

This call to `add` returns `8`, as expected.

Curried functions are interesting and useful because new functions can be constructed from them by partial evaluation. **Partial evaluation** means that the function is evaluated with actual parameters for one or more of the leftmost formal parameters. For example, we could define a new function as follows:

```
fun add5 x = add 5 x;
```

The `add5` function takes the actual parameter `5` and evaluates the `add` function with `5` as the value of its first formal parameter. It returns a function that adds `5` to its single parameter, as in the following:

```
val num = add5 10;
```

The value of `num` is now `15`. We could create any number of new functions from the curried function `add` to add any specific number to a given parameter.

Curried functions also can be written in Scheme, Haskell, and F#. Consider the following Scheme function:

```
(DEFINE (add x y) (+ x y))
```

A curried version of this would be as follows:

```
DEFINE (add y) (LAMBDA (x) (+ y x)))
```

This can be called as follows:

```
((add 3) 4)
```

ML has enumerated types, arrays, and tuples. ML also has exception

handling and a module facility for implementing abstract data types.

ML has had a significant impact on the evolution of programming languages. For language researchers, it has become one of the most studied languages. Furthermore, it has spawned several subsequent languages, among them Haskell, Caml, OCaml, and F#.

15.8 Haskell

Haskell (Thompson, 1999) is similar to ML in that it uses a similar syntax, is static scoped, is strongly typed, and uses the same type inferencing method. There are three characteristics of Haskell that set it apart from ML: First, functions in Haskell can be overloaded (functions in ML cannot). Second, nonstrict semantics are used in Haskell, whereas in ML (and most other programming languages) strict semantics are used. Third, Haskell is a pure functional programming language, meaning it has no expressions or statements that have side effects, whereas ML allows some side effects (for example, ML has mutable arrays). Both nonstrict semantics and function overloading are further discussed later in this section.

The code in this section is written in version 1.4 of Haskell.

Consider the following definition of the factorial function, which uses pattern matching on its parameters:

```
fact 0 = 1
fact 1 = 1
fact n = n * fact (n - 1)
```

Note the differences in syntax between this definition and its ML version in Section 15.7. First, there is no reserved word to introduce the function definition (**fun** in ML). Second, alternative definitions of functions (with different formal parameters) all have the same appearance.

Using pattern matching, we can define a function for computing the nth Fibonacci number with the following:

```
fib 0 = 1
fib 1 = 1
fib (n + 2) = fib (n + 1) + fib n
```

Guards can be added to lines of a function definition to specify the circumstances under which the definition can be applied. For example,

```
fact n
  | n == 0 = 1
  | n == 1 = 1
  | n > 1 = n * fact(n - 1)
```

This definition of factorial is more precise than the previous one, as it restricts the range of actual parameter values to those for which it works. This form of a function definition is called a *conditional expression*, after the mathematical expressions on which it is based.

An **`otherwise`** can appear as the last condition in a conditional expression, with the obvious semantics. For example,

```
sub n
  | n < 10    = 0
  | n > 100   = 2
  | otherwise = 1
```

Notice the similarity between the guards here and the guarded commands discussed in Chapter 8.

Consider the following function definition, whose purpose is the same as the corresponding ML function in Section 15.7:

```
square x = x * x
```

In this case, however, because of Haskell's support for polymorphism, this function can take a parameter of any numeric type.

As with ML, lists are written in brackets in Haskell, as in

```
colors = [”blue”, ”green”, ”red”, ”yellow”]
```

Haskell includes a collection of list operators. For example, lists can be catenated with `++`, `:` serves as an infix version of `CONS`, and `..` is used to specify an arithmetic series in a list. For example,

```
5:[2, 7, 9] results in [5, 2, 7, 9]
[1, 3..11] results in [1, 3, 5, 7, 9, 11]
[1, 3, 5] ++ [2, 4, 6] results in [1, 3, 5, 2, 4, 6]
```

Notice that the : operator is just like ML's :: operator.[10] Using : and pattern matching, we can define a simple function to compute the product of a given list of numbers:

10. It is interesting that ML uses : for attaching a type name to a name and :: for CONS, while Haskell uses these two operators in exactly opposite ways.

```
product [] = 1
product (a:x) = a * product x
```

Using `product`, we can write a factorial function in the simpler form

```
fact n = product [1..n]
```

Haskell includes a **`let`** construct that is similar to ML's **`let`** and **`val`**. For example, we could write

```
quadratic_root a b c =
    let minus_b_over_2a = - b / (2.0 * a)
     root_part_over_2a =
                sqrt(b ^ 2 - 4.0 * a * c) / (2.0 * a)
    in
     minus_b_over_2a - root_part_over_2a,
     minus_b_over_2a + root_part_over_2a
```

Haskell's list comprehensions were introduced in Chapter 6. For example, consider the following example of a list comprehension:

```
[n * n * n | n <- [1..50]]
```

This defines a list of the cubes of the numbers from 1 to 50. It is read as "a list of all `n*n*n` such that `n` is taken from the range of 1 to 50." In this case, the qualifier is in the form of a **generator**. It generates the numbers from `1` to `50`. In other cases, the qualifiers are in the form of Boolean expressions and they are called **tests**. This notation can be used to describe algorithms for doing many things, such as finding permutations of lists and sorting lists. For example, consider the following function, which when given a number `n` returns a list of all its factors:

```
factors n = [ i | i <-  [1..n `div` 2], n `mod` i == 0]
```

The list comprehension in `factors` creates a list of numbers, each temporarily bound to the name `i`, ranging from `1` to `n/2`, such that `n `mod` i` is zero. This is indeed a very exacting and short definition of the factors of a given number. The backticks (backward apostrophes) surrounding **`div`** and **`mod`** are used to specify the infix use of these functions. When they are called in functional notation, as in **`div`** `n 2`, the backticks are not used.

Next, consider the concision of Haskell illustrated in the following implementation of the quicksort algorithm:

```
sort [] = []
sort (h:t) = sort [b | b <- t, b <- h]
             ++ [h] ++
             sort [b | b <- t, b > h]
```

In this program, the set of list elements that are smaller or equal to the list head are sorted and catenated with the head element, then the set of elements that are greater than the list head are sorted and catenated onto the previous result. This definition of quicksort is significantly shorter and simpler than the same algorithm coded in an imperative language.

A programming language is **strict** if it requires all actual parameters to be fully evaluated, which ensures that the value of a function does not depend on the order in which the parameters are evaluated. A language is **nonstrict** if it does not have the strict requirement. Nonstrict languages can have several distinct advantages over strict languages. First, nonstrict languages are generally more efficient, because some evaluation is avoided.11 Second, some interesting capabilities are possible with nonstrict languages that are not possible with strict languages. Among these are infinite lists. Nonstrict languages can use an evaluation form called **lazy evaluation**, which means that expressions are evaluated only if and when their values are needed.

11. Notice how this is related to short-circuit evaluation of Boolean expressions, which is done in some imperative languages.

Recall that in Scheme the parameters to a function are fully evaluated before the function is called, so it has strict semantics. Lazy evaluation means that an actual parameter is evaluated only when its value is necessary to evaluate the function. So, if a function has two parameters, but on a particular

execution of the function the first parameter is not used, the actual parameter passed for that execution will not be evaluated. Furthermore, if only a part of an actual parameter must be evaluated for an execution of the function, the rest is left unevaluated. Finally, actual parameters are evaluated only once, if at all, even if the same actual parameter appears more than once in a function call.

As stated previously, lazy evaluation allows one to define infinite data structures. For example, consider the following:

```
positives = [0..]
evens = [2, 4..]
squares = [n * n | n <- [0..]]
```

Of course, no computer can actually represent all of the numbers of these lists, but that does not prevent their use if lazy evaluation is used. For example, if we wanted to know if a particular number was a perfect square, we could check the `squares` list with a membership function. Suppose we had a predicate function named `member` that determined whether a given atom is contained a given list. Then we could use it as in

```
member 16 squares
```

which would return `True`. The `squares` definition would be evaluated until the `16` was found. The `member` function would need to be carefully written. Specifically, suppose it were defined as follows:

```
member b [] = False
member b (a:x)= (a == b) || member b x
```

The second line of this definition breaks the first parameter into its head and tail. Its return value is true if either the head matches the element for which it is searching (`b`) or if the recursive call with the tail of the list returns `True`.

This definition of `member` would work correctly with `squares` only if the given number were a perfect square. If not, `squares` would keep generating squares forever, or until some memory limitation was reached, looking for the given number in the list. The following function performs the membership test of an ordered list, abandoning the search and returning

`False` if a number greater than the searched-for number is found.12

12. This assumes that the list is in ascending order.

```
member2 n (m:x)
  | m < n     = member2 n x
  | m == n    = True
  | otherwise = False
```

Lazy evaluation sometimes provides a modularization tool. Suppose that in a program there is a call to function `f` and the parameter to `f` is the return value of a function `g`.13 So, we have `f(g(x))`. Further suppose that `g` produces a large amount of data, a little at a time, and that `f` must then process this data, a little at a time. In a conventional imperative language, `g` would run on the whole input producing a file of its output. Then `f` would run using the file as its input. This approach requires the time to both write and read the file, as well as the storage for the file. With lazy evaluation, the executions of `f` and `g` implicitly would be tightly synchronized. Function `g` will execute only long enough to produce enough data for `f` to begin its processing. When `f` is ready for more data, `g` will be restarted to produce more, while `f` waits. If `f` terminates without getting all of `g`'s output, `g` is aborted, thereby avoiding useless computation. Also, `g` need not be a terminating function, perhaps because it produces an infinite amount of output. `g` will be forced to terminate when `f` terminates. So, under lazy evaluation, `g` runs as little as possible. This evaluation process supports the modularization of programs into generator units and selector units, where the generator produces a large number of possible results and the selector chooses the appropriate subset.

13. This example appears in Hughes (1989).

Lazy evaluation is not without its costs. It would certainly be surprising if such expressive power and flexibility were free. In this case, the cost is in a far more complicated semantics, which results in much slower speed of execution.

15.9 F#

F# is a .NET functional programming language whose core is based on OCaml, which is a descendant of ML and Haskell. Although it is fundamentally a functional language, it includes imperative features and supports object-oriented programming. One of the most important characteristics of F# is that it has a full-featured IDE, an extensive library of utilities that supports imperative, object-oriented, and functional programming, and has interoperability with a collection of nonfunctional languages (all of the .NET languages).

F# is a first-class .NET language. This means that F# programs can interact in every way with other .NET languages. For example, F# classes can be used and subclassed by programs in other languages, and vice versa. Furthermore, F# programs have access to all of the .NET Framework APIs. The F# implementation is available free from Microsoft (`http://research.microsoft.com/fsharp/fsharp.aspx`). It is also supported by Visual Studio.

F# includes a variety of data types. Among these are tuples, like those of Python and the functional languages ML and Haskell, lists, discriminated unions, an expansion of ML's unions, and records, like those of ML, which are like tuples except the components are named. F# has both mutable and immutable arrays.

Recall from Chapter 6, that F#'s lists are similar to those of ML, except that the elements are separated by semicolons and `hd` and `tl` must be called as methods of `List`.

F# supports sequence values, which are types from the .NET namespace `System.Collections.Generic.IEnumerable`. In F#, sequences are abbreviated as `seq<type>`, where <type> indicates the type of the generic. For example, the type `seq<int>` is a sequence of integer values. Sequence values can be created with generators and they can be iterated. The simplest sequences are generated with range expressions, as in the following example:

```
let x = seq {1..4};;
```

In the examples of F#, we assume that the interactive interpreter is used, which requires the two semicolons at the end of each statement. The expression above generates `seq[1; 2; 3; 4]`. (List and sequence elements are separated by semicolons.) The generation of a sequence is lazy; for example, the following defines `y` to be a very long sequence, but only the needed elements are generated. For display, only the first four are generated.

```
let y = seq {0..100000000};;
y;;
val it: seq<int> = seq[0; 1; 2; 3;...]
```

The first line above defines `y`; the second line requests that the value of `y` be displayed; the third is the output of the F# interactive interpreter.

The default step size for integer sequence definitions is `1`, but it can be set by including it in the middle of the range specification, as in the following example:

```
seq {1..2..7};;
```

This generates `seq [1; 3; 5; 7]`.

The values of a sequence can be iterated with a **`for-in`** construct, as in the following example:

```
let seq1 = seq {0..3..11};;
for value in seq1 do printfn ”value = %d” value;;
```

This produces the following:

```
value = 0
value = 3
value = 6
value = 9
```

Iterators can also be used to create sequences, as in the following example:

```
let cubes = seq {for i in 1..5 -> (i, i * i * i)};;
```

This generates the following list of tuples:

```
seq [(1, 1); (2, 8); (3, 27); (4, 64); (5, 125)]
```

This use of iterators to generate collections is a form of list comprehension.

Sequencing can also be used to generate lists and arrays, although in these cases the generation is not lazy. In fact, the primary difference between lists and sequences in F# is that sequences are lazy, and thus can be infinite, whereas lists are not lazy. Lists are in their entirety stored in memory. That is not the case with sequences.

The functions of F# are similar to those of ML and Haskell. If named, they are defined with **`let`** statements. If unnamed, which means technically they are lambda expressions, they are defined with the **`fun`** reserved word. The following lambda expression illustrates their syntax:

```
(fun  a b -> a / b)
```

Note that there is no difference between a name defined with **`let`** and a function without parameters defined with **`let`**.

Indentation is used to show the extent of a function definition. For example, consider the following function definition:

```
let f =
    let pi = 3.14159
    let twoPi = 2.0 * pi
    twoPi;;
```

Note that F#, like ML, does not coerce numeric values, so if this function used `2` in the second-last line, rather than `2.0`, an error would be reported.

If a function is recursive, the reserved word **`rec`** must precede its name in its definition. Following is an F# version of factorial:

```
let rec factorial x =
    if x <= 1  then 1
    else n * factorial(n - 1)
```

Names defined in functions can be outscoped, which means they can be

redefined, which ends their former scope. For example, we could have the following:

```
let x4 x =
    let x = x * x
    let x = x * x
    x;;
```

In this function, the first **let** in the body of the x4 function creates a new version of x, defining it to have the value of the square of the parameter x. This terminates the scope of the parameter. So, the second **let** in the function body uses the new x in its right side and creates yet another version of x, thereby terminating the scope of the x created in the previous **let**.

There are two important functional operators in F#, pipeline (|>) and function composition (>>). The pipeline operator is a binary operator that sends the value of its left operand, which is an expression, to the last parameter of the function call, which is the right operand. It is used to chain together function calls while flowing the data being processed to each call. Consider the following example code, which uses the high-order functions filter and map:

```
let myNums = [1; 2; 3; 4; 5]
let evensTimesFive = myNums
    |> List.filter (fun n -> n % 2 = 0)
    |> List.map (fun n -> 5 * n)
```

The evensTimesFive function begins with the list myNums, filters out the numbers that are not even with filter, and uses map to map a lambda expression that multiplies the numbers in a given list by five. The return value of evensTimesFive is [10; 20].

The function composition operator builds a function that applies its left operand to a given parameter, which is a function, and then passes the result returned from that function to its right operand, which is also a function. So, the F# expression (f >> g)x is equivalent to the mathematical expression g(f(x)).

Like ML, F# supports curried functions and partial evaluation. The ML example in Section 15.7 could be written in F# as follows:

```
let add a b = a + b;;
let add5 = add 5;;
```

Note that, unlike ML, the syntax of the formal parameter list in F# is the same for all functions, so all functions with more than one parameter can be curried.

F# is interesting for several reasons: First, it builds on the past functional languages as a functional language. Second, it supports virtually all programming methodologies in widespread use today. Third, it is the first functional language that is designed for interoperability with other widely used languages. Fourth, it starts out with an elaborate and well-developed IDE and library of utility software with .NET and its framework.

15.10 Support for Functional Programming in Primarily Imperative Languages

Imperative programming languages have typically provided only limited support for functional programming. That limited support has resulted in little use of those languages for functional programming. The most important restriction, related to functional programming, of imperative languages of the past was the lack of support for higher-order functions.

One indication of the increasing interest and use of functional programming is the partial support for it that has begun to appear over the last decade in programming languages that are primarily imperative. For example, anonymous functions, which are like lambda expressions, are now part of JavaScript, Python, Ruby, Java, and C#.

In JavaScript, named functions are defined with the following syntax:

```
function name (formal-parameters) {
 body
}
```

An anonymous function is defined in JavaScript with the same syntax, except that the name of the function is omitted.

In C#, a lambda expression is an instance of a delegate. They can be anonymous or named. An anonymous lambda expression is simpler than an anonymous method because methods must define their parameter types and return type, but lambda expressions use the C# inferencing process to avoid those necessities. The syntax of an unnamed lambda expression in C# is as follows:

```
parameter(s) => expression
```

If there is more than one parameter, they must be enclosed in parentheses. If there are no parameters, empty parentheses must appear in the place of the parameters. If the system cannot infer the types of the parameters, they can be preceded by type names. The type of the return value is never specified; it is always inferred by the context of the lambda expression. The expression is either a single expression or a compound statement enclosed in braces. Such a compound statement must include a **`return`** statement.

One common use of anonymous lambda expressions is as actual parameters to methods that are specified to take delegates as parameters. For example, C# has a collection of methods for arrays that perform searching operations. For example, the `FindAll` method finds all of the elements of an array that satisfy a given instance of a delegate that takes a parameter of the type of the array's elements and returns a Boolean value. For example, we could have the following:

```
int[] numbers = {-3, 0, 4, 5, 1, 7, -3, -6, -9, 0, 3};
int[] positives = Array.FindAll(numbers, n => n > 0);
// Now, positives is {4, 5, 1, 7, 3}
```

Lambda expressions in C# can also be named. The language has generic delegates that make defining such lambda expressions simple, although they do not cover all possibilities. One commonly used generic delegate is `Func`, which can take up to sixteen generic parameters for the parameters of the lambda expression, plus one more for the return type. For example, consider the following example of a named lambda expression and an invocation of it:

```
Func<int, int, int> eval1 = (a, b) => 3 * a + (b / 2);
int result = eval1(6, 22);
```

C# lambda expressions can access variables defined outside their definitions. When they do, the lifetimes of the accessed external variables, which are called **captured variables**, are extended so that they still exist when the lambda expression is used. A lambda expression that captures outside variables is a closure.

Lambda expressions were added to Java 8. The general syntax of these expressions is like that of C#, except that `->` is used instead of `=>`. The syntax of parameters, the inferencing of parameter types and the return type, and the

expression or block with a **`return`** are the same as with C#. Prior to Java 8, there was no convenient way to pass a block of code to a method or have the method return a block of code.14

14. One inconvenient way was to define a class with a method that contained the code, instantiate the class, and pass a reference to it.

Python's lambda expressions define simple one-statement anonymous functions. The syntax of a lambda expression in Python is exemplified by the following:

```
lambda a, b : 2 * a - b
```

Note that the formal parameters are separated from function body by a colon.

Python includes the higher-order functions `filter` and `map`. Both often use lambda expressions as their first parameter. The second parameter of these is a sequence type, and both return the same sequence type as their second parameter. In Python, strings, lists, and tuples are considered sequences. Consider the following example of using the map function in Python:

```
map(lambda x: x ** 3, [2, 4, 6, 8])
```

This call returns `[8, 64, 216, 512]`.

Python also supports partial function applications. Consider the following example:

```
from operator import add
add5 = partial (add, 5)
```

The **`from`** declaration here imports the functional version of the addition operator, which is named `add`, from the `operator` module.

After defining `add5`, it can be used with one parameter, as in the following:

```
add5(15)
```

This call returns `20`.

As described in Chapter 6, Python includes lists and list comprehensions.

Ruby's blocks are effectively subprograms that are sent to methods, which makes the method a higher-order subprogram. A Ruby block can be converted to a subprogram object with **`lambda`**. For example, consider the following:

```
times = lambda {|a, b| a * b}
```

Following is an example of using `times`:

```
x = times.(3, 4)
```

This sets `x` to `12`. The `times` object can be curried with the following:

```
times5 = times.curry.(5)
```

This function can be used as in the following:

```
x5 = times5.(3)
```

This sets `x5` to `15`.

15.11 A Comparison of Functional and Imperative Languages

This section discusses some of the differences between imperative and functional languages.

Functional languages can have a very simple syntactic structure. The list structure of Lisp, which is used for both code and data, clearly illustrates this. The syntax of the imperative languages is much more complex. This makes them more difficult to learn and to use.

The semantics of functional languages is also simpler than that of the imperative languages. For example, in the denotational semantics description of an imperative loop construct given in Section 3.5.2, the loop is converted from an iterative construct to a recursive construct. This conversion is unnecessary in a pure functional language, in which there is no iteration. Furthermore, we assumed there were no expression side effects in all of the denotational semantic descriptions of imperative constructs in Chapter 3. This restriction is unrealistic for imperative languages, because all of the C-based languages include expression side effects. This restriction is not needed for the denotational descriptions of pure functional languages.

Some in the functional programming community have claimed that the use of functional programming results in an order-of-magnitude increase in productivity, largely due to functional programs being claimed to be only 10 percent as large as their imperative counterparts. While such numbers have been actually shown for certain problem areas, for other problem areas, functional programs are more like 25 percent as large as imperative solutions to the same problems (Wadler, 1998). These factors allow proponents of functional programming to claim productivity advantages over imperative programming of 4 to 10 times. However, program size alone is not necessarily a good measure of productivity. Certainly not all lines of source code have equal complexity, nor do they take the same amount of time to produce. In fact, because of the necessity of dealing with variables,

imperative programs have many trivially simple lines for initializing and making small changes to variables.

Execution efficiency is another basis for comparison. When functional programs are interpreted, they are of course much slower than their compiled imperative counterparts. However, there are now compilers for most functional languages, so that execution speed disparities between functional languages and compiled imperative languages are no longer so great. One might be tempted to say that because functional programs are significantly smaller than equivalent imperative programs, they should execute much faster than the imperative programs. However, this often is not the case, because of a collection of language characteristics of the functional languages, such as lazy evaluation, that have a negative impact on execution efficiency. Considering the relative efficiency of functional and imperative programs, it is reasonable to estimate that an average functional program will execute in about twice the time of its imperative counterpart (Wadler, 1998). This may sound like a significant difference, one that would often lead one to dismiss the functional languages for a given application. However, this factor-of-two difference is important only in situations where execution speed is of the utmost importance. There are many situations where a factor of two in execution speed is not considered important. For example, consider that many programs written in imperative languages, such as the Web software written in JavaScript and PHP, are interpreted and therefore are much slower than equivalent compiled versions. For these applications, execution speed is not the first priority.

Another source of the difference in execution efficiency between functional and imperative programs is the fact that imperative languages were designed to run efficiently on von Neumann architecture computers, while the design of functional languages is based on mathematical functions. This gives the imperative languages a large advantage.

Functional languages have a potential advantage in readability. In many imperative programs, the details of dealing with variables obscure the logic of the program. Consider a function that computes the sum of the cubes of the first n positive integers. In C, such a function would likely appear similar to the following:

```
int sum_cubes(int  n){
  int sum = 0;
  for(int index = 1; index <= n; index++)
    sum += index * index * index;
  return sum;
}
```

In Haskell, the function could be:

```
sumCubes n = sum (map (^3) [1..n])
```

This version simply specifies three steps:

1. Build the list of numbers (`[1..n]`).

2. Create a new list by mapping a function that computes the cube of a number onto each number in the list.

3. Sum the new list.

Because of the lack of details of variables and iteration control, this version is more readable than the C version.15

15. Of course, the C version could have been written in a more functional style, but most C programmers probably would not write it that way.

Concurrent execution in the imperative languages is difficult to design and difficult to use, as we saw in Chapter 13. In an imperative language, the programmer must make a static division of the program into its concurrent parts, which are then written as tasks, whose execution often must be synchronized. This can be a complicated process. Programs in functional languages are naturally divided into functions. In a pure functional language, these functions are independent in the sense that they do not create side effects and their operations do not depend on any nonlocal or global variables. Therefore, it is much easier to determine which of them can be concurrently executed. The actual parameter expressions in calls often can be evaluated concurrently. Simply by specifying that it can be done, a function can be implicitly evaluated in a separate thread, as in Multilisp. And, of course, access to shared immutable data does not require synchronization.

One simple factor that strongly affects the complexity of imperative, or procedural programming, is the necessary attention of the programmer to the state of the program at each step of its development. In a large program, the state of the program is a large number of values (for the large number of program variables). In pure functional programming, there is no state; hence, no need to devote attention to keeping it in mind.

It is not a simple matter to determine precisely why functional languages have not attained greater popularity. The inefficiency of the early implementations was clearly a factor then, and it is likely that at least some contemporary imperative programmers still believe that programs written in functional languages are slow. In addition, the vast majority of programmers learn programming using imperative languages, which makes functional programs appear to them to be strange and difficult to understand. For many who are comfortable with imperative programming, the switch to functional programming is an unattractive and potentially difficult move. On the other hand, those who begin with a functional language never notice anything strange about functional programs.

SUMMARY

Mathematical functions are named or unnamed mappings that use only conditional expressions and recursion to control their evaluations. Complex functions can be defined using higher-order functions or functional forms, in which functions are used as parameters, returned values, or both.

Functional programming languages are modeled on mathematical functions. In their pure form, they do not use variables or assignment statements to produce results; rather, they use function applications, conditional expressions, and recursion for execution control and functional forms to construct complex functions. Lisp began as a purely functional language but soon acquired a number of imperative-language features added in order to increase its efficiency and ease of use.

The first version of Lisp grew out of the need for a list-processing language for AI applications. Lisp is still the most widely used language for that application area.

The first implementation of Lisp was serendipitous: The original version of EVAL was developed solely to demonstrate that a universal Lisp function could be written.

Because Lisp data and Lisp programs have the same form, it is possible to have a program build another program. The availability of EVAL allows dynamically constructed programs to be executed immediately.

Scheme is a relatively simple dialect of Lisp that uses static scoping exclusively. Like Lisp, Scheme's primary primitives include functions for constructing and dismantling lists, functions for conditional expressions, and simple predicates for numbers, symbols, and lists.

Common Lisp is a Lisp-based language that was designed to include most of the features of the Lisp dialects of the early 1980s. It allows both static- and dynamic-scoped variables and includes many imperative features. Common

Lisp uses macros to define some of its functions. Users are allowed to define their own macros. The language includes reader macros, which are also user definable. Reader macros define single-symbol macros.

ML is a static-scoped and strongly typed functional programming language that uses a syntax that is more closely related to that of an imperative language than to Lisp. It includes a type-inferencing system, exception handling, a variety of data structures, and abstract data types.

ML does not do any type coercions and does not allow function overloading. Multiple definitions of functions can be defined using pattern matching of the actual parameter form. Currying is the process of replacing a function that takes multiple parameters with one that takes a single parameter and returns a function that takes the other parameters. ML, as well as several other functional languages, supports currying.

Haskell is similar to ML, except that all expressions in Haskell are evaluated using a lazy method, which allows programs to deal with infinite lists. Haskell also supports list comprehensions, which provide a convenient and familiar syntax for describing sets. Unlike ML and Scheme, Haskell is a pure functional language.

F# is a .NET programming language that supports functional and imperative programming, including object-oriented programming. Its functional programming core is based on OCaml, a descendent of ML and Haskell. F# is supported by an elaborate and widely used IDE. It also interoperates with other .NET languages and has access to the .NET class library.

BIBLIOGRAPHIC NOTES

- The first published version of Lisp can be found in McCarthy (1960). A widely used version from the mid-1960s until the late 1970s is described in McCarthy et al. (1965) and Weissman (1967). Common Lisp is described in Steele (1990). The Scheme language is described in Dybvig (2011). ML is defined in Milner et al. (1997). Ullman (1998) is an excellent introductory textbook for ML. Programming in Haskell is introduced in Thompson (1999). F# is described in Syme et al. (2010).

- The Scheme programs in this chapter were developed using DrRacket's legacy language R5RS.

- A rigorous discussion of functional programming in general can be found in Henderson (1980). The process of implementing functional languages through graph reduction is discussed in detail in Peyton Jones (1987).

REVIEW QUESTIONS

1. Define *functional form*, *simple list*, *bound variable*, and *referential transparency*.
2. What does a lambda expression specify?
3. What data types were parts of the original Lisp?
4. In what common data structure are Lisp lists normally stored?
5. Explain why `QUOTE` is needed for a parameter that is a data list.
6. What is a simple list?
7. What does the abbreviation REPL stand for?
8. What are the three parameters to `IF`?
9. What are the differences between `=`, `EQ?`, `EQV?`, and `EQUAL`?
10. What are the differences between the evaluation method used for the Scheme special form `DEFINE` and that used for its primitive functions?
11. What are the two forms of `DEFINE`?
12. Describe the syntax and semantics of `COND`.
13. Why are `CAR` and `CDR` so named?
14. If `CONS` is called with two atoms, say `'A` and `'B`, what is the returned?
15. Describe the syntax and semantics of `LET` in Scheme.
16. What are the differences between `CONS`, `LIST`, and `APPEND`?
17. Describe the syntax and semantics of `mapcar` in Scheme.

18. What is tail recursion? Why is it important to define functions that use recursion to specify repetition to be tail recursive?

19. Why were imperative features added to most dialects of Lisp?

20. In what ways are Common Lisp and Scheme opposites?

21. What scoping rule is used in Scheme? In Common Lisp? In ML? In Haskell? In F#?

22. What happens during the reader phase of a Common Lisp language processor?

23. What are two ways that ML is fundamentally different from Scheme?

24. What is stored in an ML evaluation environment?

25. What is the difference between an ML **`val`** statement and an assignment statement in C?

26. What is type inferencing, as used in ML?

27. What is the use of the **`fn`** reserved word in ML?

28. Can ML functions that deal with scalar numerics be generic?

29. What is a curried function?

30. What does partial evaluation mean?

31. Describe the actions of the ML `filter` function.

32. What operator does ML use for Scheme's CAR?

33. What operator does ML use for functional composition?

34. What are the three characteristics of Haskell that make it different from ML?

35. What does lazy evaluation mean?

36. What is a strict programming language?

37. What programming paradigms are supported by F#?

38. With what other programming languages can F# interoperate?

39. What does F#'s `let` do?

40. How is the scope of a F# `let` construct terminated?

41. What is the underlying difference between a sequence and a list in F#?

42. What is the difference between the let of ML and that of F#, in terms of extent?

43. What is the syntax of a lambda expression in F#?

44. Does F# coerce numeric values in expressions? Argue in support of the design choice.

45. What support does Python provide for functional programming?

46. What function in Ruby is used to create a curried function?

47. Is the use of functional programming expanding or shrinking?

48. What is one characteristic of functional programming languages that makes their semantics simpler than that of imperative languages?

49. What is the flaw in using lines of code to compare the productivity of functional languages and that of imperative languages?

50. Why can concurrency be easier with functional languages than imperative languages?

PROBLEM SET

1. Read John Backus's paper on FP (Backus, 1978) and compare the features of Scheme discussed in this chapter with the corresponding features of FP.

2. Find definitions of the Scheme functions `EVAL` and `APPLY`, and explain their actions.

3. One of the most modern and complete programming environments is the INTERLISP system for Lisp, as described in "The INTERLISP Programming Environment," by Teitelmen and Masinter (*IEEE Computer*, Vol. 14, No. 4, April 1981). Read this article carefully and compare the difficulty of writing Lisp programs on your system with that of using INTERLISP (assuming that you do not normally use INTERLISP).

4. Refer to a book on Lisp programming and determine what arguments support the inclusion of the `PROG` feature in Lisp.

5. Find at least one example of a typed functional programming language being used to build a commercial system in each of the following areas: database processing, financial modeling, statistical analysis, and bioinformatics.

6. A functional language could use some data structure other than the list. For example, it could use strings of single-character symbols. What primitives would such a language have in place of the `CAR`, `CDR`, and `CONS` primitives of Scheme?

7. Make a list of the features of F# that are not in ML.

8. If Scheme were a pure functional language, could it include `DISPLAY`? Why or why not?

9. What does the following Scheme function do?

```
(define (y s lis)
  (cond
    ((null? lis) '() )
    ((equal? s (car lis)) lis)
    (else (y s (cdr lis)))
))
```

10. What does the following Scheme function do?

```
(define (x lis)
  (cond
    ((null? lis) 0)
    ((not (list? (car lis)))
       (cond
         ((eq? (car lis) #f) (x (cdr lis)))
         (else (+ 1 (x (cdr lis))))))
    (else (+ (x (car lis)) (x (cdr lis))))
```

PROGRAMMING EXERCISES

1. Write a Scheme function that computes the volume of a sphere, given its radius.

2. Write a Scheme function that computes the real roots of a given quadratic equation. If the roots are complex, the function must display a message indicating that. This function must use an `IF` function. The three parameters to the function are the three coefficients of the quadratic equation.

3. Repeat Programming Exercise 2 using a `COND` function, rather than an `IF` function.

4. Write a Scheme function that takes two numeric parameters, `A` and `B`, and returns `A` raised to the `B` power.

5. Write a Scheme function that returns the number of zeros in a given simple list of numbers.

6. Write a Scheme function that takes a simple list of numbers as a parameter and returns a list with the largest and smallest numbers in the input list.

7. Write a Scheme function that takes a list and an atom as parameters and returns a list identical to its parameter list except with all top-level instances of the given atom deleted.

8. Write a Scheme function that takes a list as a parameter and returns a list identical to the parameter except the last element has been deleted.

9. Repeat Programming Exercise 7, except that the atom can be either an atom or a list.

10. Write a Scheme function that takes two atoms and a list as parameters and returns a list identical to the parameter list except all occurrences of

the first given atom in the list are replaced with the second given atom, no matter how deeply the first atom is nested.

11. Write a Scheme function that returns the reverse of its simple list parameter.

12. Write a Scheme predicate function that tests for the structural equality of two given lists. Two lists are structurally equal if they have the same list structure, although their atoms may be different.

13. Write a Scheme function that returns the union of two simple list parameters that represent sets.

14. Write a Scheme function with two parameters, an atom and a list, that returns a list identical to the parameter list except with all occurrences, no matter how deep, of the given atom deleted. The returned list cannot contain anything in place of the deleted atoms.

15. Write a Scheme function that takes a list as a parameter and returns a list identical to the parameter list except with the second top-level element removed. If the given list does not have two elements, the function should return `()`.

16. Write a Scheme function that takes a simple list of numbers as its parameter and returns a list identical to the parameter list except with the numbers in ascending order.

17. Write a Scheme function that takes a simple list of numbers as its parameter and returns the largest and smallest numbers in the list.

18. Write a Scheme function that takes a simple list as its parameter and returns a list of all permutations of the given list.

19. Write the quicksort algorithm in Scheme.

20. Rewrite the following Scheme function as a tail-recursive function:

```
(DEFINE (doit n)
  (IF (= n 0)
```

```
        0
        (+ n (doit (- n 1)))
    ))
```

21. Write any of the first 19 Programming Exercises in F#.

22. Write any of the first 19 Programming Exercises in ML.

16 Logic Programming Languages

The objectives of this chapter are to introduce the concepts of logic programming and logic programming languages, including a brief description of a subset of Prolog. We begin with an introduction to predicate calculus, which is the basis for logic programming languages. This is followed by a discussion of how predicate calculus can be used for automatic theorem-proving systems. Then, we present a general overview of logic programming. Next, a lengthy section introduces the basics of the Prolog programming language, including arithmetic, list processing, and a trace tool that can be used to help debug programs and also to illustrate how the Prolog system works. The final two sections describe some of the problems of Prolog as a logic language and some of the application areas in which Prolog has been used.

16.1 Introduction

Chapter 15 discusses the functional programming paradigm, which is significantly different from the software development methodologies used with the imperative languages. In this chapter, we describe another different programming methodology. In this case, the approach is to express programs in a form of symbolic logic and use a logical inferencing process to produce results. Logic programs are declarative rather than procedural, which means that only the specifications of the desired results are stated rather than detailed procedures for producing them. Programs in logic programming languages are collections of facts and rules. Such a program is used by asking it questions, which it attempts to answer by consulting the facts and rules. "Consulting" is perhaps misleading here, for the process is far more complex than that word connotes. This approach to problem solving may sound like it addresses only a very narrow category of problems, but it is more flexible than might be thought.

Programming that uses a form of symbolic logic as a programming language is often called **logic programming**, and languages based on symbolic logic are called **logic programming languages**, or **declarative languages**. We have chosen to describe the logic programming language Prolog, because it is the only widely used logic language.

The syntax of logic programming languages is remarkably different from that of the imperative and functional languages. The semantics of logic programs also bears little resemblance to that of imperative-language programs. These observations should lead the reader to some curiosity about the nature of logic programming and declarative languages.

16.2 A Brief Introduction to Predicate Calculus

Before we can discuss logic programming, we must briefly investigate its basis, which is formal logic. This is not our first contact with formal logic in this text; it was used extensively in the axiomatic semantics described in Chapter 3.

A **proposition** can be thought of as a logical statement that may or may not be true. It consists of objects and the relationships among objects. Formal logic was developed to provide a method for describing propositions, with the goal of allowing those formally stated propositions to be checked for validity.

Symbolic logic can be used for the three basic needs of formal logic: to express propositions, to express the relationships between propositions, and to describe how new propositions can be inferred from other propositions that are assumed to be true.

There is a close relationship between formal logic and mathematics. In fact, much of mathematics can be thought of in terms of logic. The fundamental axioms of number and set theory are the initial set of propositions, which are assumed to be true. Theorems are the additional propositions that can be inferred from the initial set.

The particular form of symbolic logic that is used for logic programming is called **first-order predicate calculus** (though it is a bit imprecise, we will usually refer to it as *predicate calculus*). In the following subsections, we present a brief look at predicate calculus. Our goal is to lay the groundwork for a discussion of logic programming and the logic programming language Prolog.

16.2.1 Propositions

The objects in logic programming propositions are represented by simple terms, which are either constants or variables. A constant is a symbol that represents an object. A variable is a symbol that can represent different objects at different times, although in a sense that is far closer to mathematics than the variables in an imperative programming language.

The simplest propositions, which are called **atomic propositions**, consist of compound terms. A **compound term** is one element of a mathematical relation, written in a form that has the appearance of mathematical function notation. Recall from Chapter 15 that a mathematical function is a mapping, which can be represented either as an expression or as a table or list of tuples. Compound terms are elements of the tabular definition of a function.

A compound term is composed of two parts: a **functor**, which is the function symbol that names the relation, and an ordered list of parameters, which together represent an element of the relation. A compound term with a single parameter is a 1-tuple; one with two parameters is a 2-tuple, and so forth. For example, we might have the two propositions

- man(jake)
- like(bob, steak)

which state that {jake} is a 1-tuple in the relation named man, and that {bob, steak} is a 2-tuple in the relation named like. If we added the proposition

- man(fred)

to the two previous propositions, then the relation man would have two distinct elements, {jake} and {fred}. All of the simple terms in these propositions—man, jake, like, bob, and steak—are constants. Note that these propositions have no intrinsic semantics. They mean whatever we want them to mean. For example, the second example may mean that bob likes steak, or that steak likes bob, or that bob is in some way similar to a steak.

Propositions can be stated in two modes: one in which the proposition is defined to be true, and one in which the truth of the proposition is something that is to be determined. In other words, propositions either can be facts or

queries. The example propositions above could be either.

Compound propositions have two or more atomic propositions, which are connected by logical connectors, or operators, in the same way compound logic expressions are constructed in imperative languages. The names, symbols, and meanings of the predicate calculus logical connectors are as follows:

Name	*Symbol*	*Example*	*Meaning*
negation	⊐	⊐ a	not *a*
conjunction	⋂	*a* ⋂ *b*	*a* and *b*
disjunction	⋃	*a* ⋃ *b*	*a* or *b*
equivalence	≡	*a* ≡ *b*	*a* is equivalent to *b*
implication	⊃	*a* ⊃ *b*	*a* implies *b*
	⊂	*a* ⊂ *b*	*b* implies *a*

The following are examples of compound propositions:

a ∩ b ⊃ c a ∩⊐b⊃ d

The ⊐ operator has the highest precedence. The operators ∩, ∪, and ≡ all have higher precedence than ⊃ and ⊂. So, the second example above is equivalent to

(a ∩(⊐ b)) ⊃ d

Variables can appear in propositions but only when introduced by special symbols called *quantifiers*. Predicate calculus includes two quantifiers, as described below, where *X* is a variable and *P* is a proposition:

Name	*Example*	*Meaning*
universal	∀ *X.P*	For all *X*, *P* is true.
existential	∃ *X.P*	There exists a value of *X* such that *P* is true.

The period between *X* and *P* simply separates the variable from the proposition. For example, consider the following:

- $\forall$ X. (woman (*X*) $\supset$ human (*X*))
- $\exists$ X. (mother (mary, *X*) $\cap$ male (*X*))

The first of these propositions means that for any value of *X*, if *X* is a woman, then *X* is a human. The second means that there exists a value of *X* such that mary is the mother of *X* and *X* is a male; in other words, mary has a son. The scope of the universal and existential quantifiers is the atomic propositions to which they are attached. This scope can be extended using parentheses, as in the two compound propositions just described. So, the universal and existential quantifiers have higher precedence than any of the operators.

16.2.2 Clausal Form

We are discussing predicate calculus because it is the basis for logic programming languages. As with other languages, logic languages are best in their simplest form, meaning that redundancy should be minimized.

One problem with predicate calculus as we have described it thus far is that there are too many different ways of stating propositions that have the same meaning; that is, there is a great deal of redundancy. This is not such a problem for logicians, but if predicate calculus is to be used in an automated (computerized) system, it is a serious problem. To simplify matters, a standard form for propositions is desirable. Clausal form, which is a relatively simple form of propositions, is one such standard form. All propositions can be expressed in clausal form. A proposition in clausal form has the following general syntax:

B1 $\cup$ B2 $\cup$ … $\cup$ Bn $\subset$ A1 $\cap$ A2 $\cap$ … $\cap$ Am

in which the *A*'s and *B*'s are terms. The meaning of this clausal form proposition is as follows: If all of the *A*'s are true, then at least one *B* is true. The primary characteristics of clausal form propositions are the following:

Existential quantifiers are not required; universal quantifiers are implicit in the use of variables in the atomic propositions; and no operators other than conjunction and disjunction are required. Also, conjunction and disjunction need appear only in the order shown in the general clausal form: disjunction on the left side and conjunction on the right side. All predicate calculus propositions can be algorithmically converted to clausal form. Nilsson (1971) gives proof that this can be done, as well as a simple conversion algorithm for doing it.

The right side of a clausal form proposition is called the **antecedent**. The left side is called the **consequent** because it is the consequence of the truth of the antecedent. As examples of clausal form propositions, consider the following:

- likes (bob, trout) $\subset$ likes (bob, fish) $\cap$ fish (trout)
- father (louis, al) $\cup$ father (louis, violet) $\subset$
- father (al, bob) $\cap$ mother (violet, bob) $\cap$ grandfather (louis, bob)

The English version of the first of these states that if bob likes fish and a trout is a fish, then bob likes trout. The second states that if al is bob's father and violet is bob's mother and louis is bob's grandfather, then louis is either al's father or violet's father.

16.3 Predicate Calculus and Proving Theorems

Predicate calculus provides a method of expressing collections of propositions. One use of collections of propositions is to determine whether any interesting or useful facts can be inferred from them. This is exactly analogous to the work of mathematicians, who strive to discover new theorems that can be inferred from known axioms and theorems.

The early days of computer science (the 1950s and early 1960s) saw a great deal of interest in automating the theorem-proving process. One of the most significant breakthroughs in automatic theorem proving was the discovery of the resolution principle by Alan Robinson (1965) at Syracuse University.

Resolution is an inference rule that allows inferred propositions to be computed from given propositions, thus providing a method with potential application to automatic theorem proving. Resolution was devised to be applied to propositions in clausal form. The concept of resolution is the following: Suppose there are two propositions with the forms

$P1 \subset P2$ $Q1 \subset Q2$

Their meaning is that P2 implies P1 and Q2 implies Q1. Furthermore, suppose that P1 is identical to Q2, so that we could rename P1 and Q2 as *T*. Then, we could rewrite the two propositions as

$T \subset P2$ $Q1 \subset T$

Now, because P2 implies *T* and *T* implies Q1, it is logically obvious that P2 implies Q1, which we could write as

$Q1 \subset P2$

The process of inferring this proposition from the original two propositions is resolution.

As another example, consider the two propositions:

- older (joanne, jake) $\subset$ mother (joanne, jake)
- wiser (joanne, jake) $\subset$ older (joanne, jake)

From these propositions, the following proposition can be constructed using resolution:

- wiser(joanne, jake) $\subset$ mother(joanne, jake)

The mechanics of this resolution construction are simple: The terms of the left sides of the two clausal propositions are OR'd together to make the left side of the new proposition. Then the right sides of the two clausal propositions are AND'd together to get the right side of the new proposition. Next, any term that appears on both sides of the new proposition is removed from both sides. The process is exactly the same when the propositions have multiple terms on either or both sides. The left side of the new inferred proposition initially contains all of the terms of the left sides of the two given propositions. The new right side is similarly constructed. Then the term that appears on both sides of the new proposition is removed. For example, if we have

- father(bob, jake) $\cup$ mother(bob, jake) $\subset$ parent(bob, jake)
- grandfather(bob, fred) $\subset$ father(bob, jake) $\cap$ father(jake, fred)

resolution says that

- mother(bob, jake) $\cup$ grandfather(bob, fred) $\subset$
- parent(bob, jake) $\cap$ father(jake, fred)

which has all but one of the atomic propositions of both of the original propositions. The one atomic proposition that allowed the operation father (bob, jake) in the left side of the first and in the right side of the second is left out. In English, we would say

if: bob is the parent of jake implies that bob is either the father or mother of jake

and: bob is the father of jake and jake is the father of fred implies that bob is the grandfather of fred

then: *if* bob is the parent of jake and jake is the father of fred *then:* either bob is jake's mother or bob is fred's grandfather

Resolution is actually more complex than these simple examples illustrate. In particular, the presence of variables in propositions requires resolution to find values for those variables that allow the matching process to succeed. This process of determining useful values for variables is called **unification**. The temporary assigning of values to variables to allow unification is called **instantiation**.

It is common for the resolution process to instantiate a variable with a value, fail to complete the required matching, and then be required to backtrack and instantiate the variable with a different value. We will discuss unification and backtracking more extensively in the context of Prolog.

A critically important property of resolution is its ability to detect any inconsistency in a given set of propositions. This is based on the formal property of resolution called **refutation complete**. What this means is that given a set of inconsistent propositions, resolution can prove them to be inconsistent. This allows resolution to be used to prove theorems, which can be done as follows: We can envision a theorem proof in terms of predicate calculus as a given set of pertinent propositions, with the negation of the theorem itself stated as a new proposition. The theorem is negated so that resolution can be used to prove the theorem by finding an inconsistency. This is proof by contradiction, a frequently used approach to proving theorems in mathematics. Typically, the original propositions are called the **hypotheses**, and the negation of the theorem is called the **goal**.

Theoretically, this process is valid and useful. The time required for resolution, however, can be a problem. Although resolution is a finite process when the set of propositions is finite, the time required to find an inconsistency in a large database of propositions may be huge.

Theorem proving is the basis for logic programming. Much of what is

computed can be couched in the form of a list of given facts and relationships as hypotheses, and a goal to be inferred from the hypotheses, using resolution.

Resolution on a hypotheses and a goal that are general propositions, even if they are in clausal form, is often not practical. Although it may be possible to prove a theorem using clausal form propositions, it may not happen in a reasonable amount of time. One way to simplify the resolution process is to restrict the form of the propositions. One useful restriction is to require the propositions to be Horn clauses. **Horn clauses** only can be in one of two forms: They have either a single atomic proposition on the left side or an empty left side.[1] The left side of a clausal form proposition is sometimes called the head, and Horn clauses with left sides are called headed Horn clauses. Headed Horn clauses are used to state relationships, such as

1. Horn clauses are named after Alfred Horn (1951), who studied clauses in this form.

- likes(bob, trout) ⊂ likes(bob, fish) ∩ fish(trout)

Horn clauses with empty left sides, which are often used to state facts, are called *headless Horn clauses*. For example,

- father(bob, jake)

Most, but not all, propositions can be stated as Horn clauses. The restriction to Horn clauses makes resolution a practical process for proving theorems.

16.4 An Overview of Logic Programming

Languages used for logic programming are called *declarative languages*, because programs written in them consist of declarations rather than assignments and control flow statements. These declarations are actually statements, or propositions, in symbolic logic.

One of the essential characteristics of logic programming languages is their semantics, which is called **declarative semantics**. The basic concept of this semantics is that there is a simple way to determine the meaning of each statement, and it does not depend on how the statement might be used to solve a problem. Declarative semantics is considerably simpler than the semantics of the imperative languages. For example, the meaning of a given proposition in a logic programming language can be concisely determined from the statement itself. In an imperative language, the semantics of a simple assignment statement requires examination of local declarations, knowledge of the scoping rules of the language, and possibly even examination of programs in other files just to determine the types of the variables in the assignment statement. Then, assuming the expression of the assignment contains variables, the execution of the program prior to the assignment statement must be traced to determine the values of those variables. The resulting action of the statement, then, depends on its run-time context. Comparing this semantics with that of a proposition in a logic language, with no need to consider textual context or execution sequences, it is clear that declarative semantics is far simpler than the semantics of imperative languages. Thus, declarative semantics is often stated as one of the advantages that declarative languages have over imperative languages (Hogger, 1984, pp. 240–241).

Programming in both imperative and functional languages is primarily procedural, which means that the programmer knows *what* is to be accomplished by a program and instructs the computer on exactly *how* the computation is to be done. In other words, the computer is treated as a simple

device that obeys orders. Everything that is computed must have every detail of that computation spelled out. Some believe that this is the essence of the difficulty of programming using imperative and functional languages.

Programming in a logic programming language is nonprocedural. Programs in such languages do not state exactly *how* a result is to be computed but rather describe the form of the result. The difference is that we assume the computer system can somehow determine *how* the result is to be computed. What is needed to provide this capability for logic programming languages is a concise means of supplying the computer with both the relevant information and a method of inference for computing desired results. Predicate calculus supplies the basic form of communication to the computer, and resolution provides the inference technique.

Sorting is commonly used to illustrate the difference between procedural and nonprocedural systems. In a language like Java, sorting is done by explaining in a Java program all of the details of some sorting algorithm to a computer that has a Java compiler. The computer, after translating the Java program into machine code or some interpretive intermediate code, follows the instructions and produces the sorted list.

In a nonprocedural language, it is necessary only to describe the characteristics of the sorted list: It is some permutation of the given list such that for each pair of adjacent elements, a given relationship holds between the two elements. To state this formally, suppose the list to be sorted is in an array named list that has a subscript range 1 . . . *n*. The concept of sorting the elements of the given list, named old_list, and placing them in a separate array, named new_list, can then be expressed as follows:

- sort(old_list, new_list) $\subset$ permute(old_list, new_list) $\cap$ sorted(new_list)
- sorted (list) $\subset \forall$ j such that 11$\leq$j<n, list(j) $\leq$list(j+1)

where permute is a predicate that returns true if its second parameter array is a permutation of its first parameter array.

From this description, the nonprocedural language system could produce the sorted list. That makes nonprocedural programming sound like the mere

production of concise software requirements specifications, which is a fair assessment. Unfortunately, however, it is not that simple. Logic programs that use only resolution face serious problems of execution efficiency. In our example of sorting, if the list is long, the number of permutations is huge, and they must be generated and tested, one by one, until the one that is in order is found—a very lengthy process. Of course, one must consider the possibility that the best form of a logic language may not yet have been determined, and good methods of creating programs in logic programming languages for large problems have not yet been developed.

16.5 The Origins of Prolog

As was stated in Chapter 2, Alain Colmerauer and Phillippe Roussel at the University of Aix-Marseille, with some assistance from Robert Kowalski at the University of Edinburgh, developed the fundamental design of Prolog. Colmerauer and Roussel were interested in natural-language processing; Kowalski was interested in automated theorem proving. The collaboration between the University of Aix-Marseille and the University of Edinburgh continued until the mid-1970s. Since then, research on the development and use of the language has progressed independently at those two locations, resulting in, among other things, two syntactically different dialects of Prolog.

The development of Prolog and other research efforts in logic programming received limited attention outside of Edinburgh and Marseille until the announcement in 1981 that the Japanese government was launching a large research project called the Fifth Generation Computing Systems (FGCS; Fuchi, 1981; Moto-oka, 1981). One of the primary objectives of the project was to develop intelligent machines, and Prolog was chosen as the basis for this effort. The announcement of FGCS aroused a sudden strong interest in artificial intelligence and logic programming in researchers and the governments of the United States and several European countries.

After a decade of effort, the FGCS project was quietly dropped. Despite the great assumed potential of logic programming and Prolog, little of great significance had been discovered. This led to the decline in the interest in and use of Prolog, although it still has its proponents.

16.6 The Basic Elements of Prolog

There are now a number of different dialects of Prolog. These can be grouped into several categories: those that grew from the Marseille group, those that came from the Edinburgh group, and some dialects that have been developed for microcomputers, such as micro-Prolog, which is described by Clark and McCabe (1984). The syntactic forms of these are somewhat different. Rather than attempt to describe the syntax of several dialects of Prolog or some hybrid of them, we have chosen one particular, widely available dialect, which is the one developed at Edinburgh. This form of the language is sometimes called **Edinburgh syntax**. Its first implementation was on a DEC System-10 (Warren et al., 1979). Prolog implementations are available for virtually all popular computer platforms, for example, from the Free Software Organization (http://www.gnu.org).

16.6.1 Terms

As with programs in other languages, Prolog programs consist of collections of statements. There are only a few kinds of statements in Prolog, but they can be complex. All Prolog statements, as well as Prolog data, are constructed from terms.

A Prolog **term** is a constant, a variable, or a structure. A constant is either an **atom** or an integer. Atoms are the symbolic values of Prolog and are similar to their counterparts in LISP. In particular, an atom is either a string of letters, digits, and underscores that begins with a lowercase letter or a string of any printable ASCII characters delimited by apostrophes.

A variable is any string of letters, digits, and underscores that begins with an uppercase letter or an underscore (_). Variables are not bound to types by declarations. The binding of a value, and thus a type, to a variable is called an **instantiation**. Instantiation occurs only in the resolution process. A variable that has not been assigned a value is called **uninstantiated**. Instantiations last

only as long as it takes to satisfy one complete goal, which involves the proof or disproof of one proposition. Prolog variables are only distant relatives, in terms of both semantics and use, to the variables in the imperative languages.

The last kind of term is called a **structure**. Structures represent the atomic propositions of predicate calculus, and their general form is the same:

```
functor(parameter list)
```

The functor is any atom and is used to identify the structure. The parameter list can be any list of atoms, variables, or other structures. As discussed at length in the following subsection, structures are the means of specifying facts in Prolog. They can also be thought of as objects, in which case they allow facts to be stated in terms of several related atoms. In this sense, structures are relations, for they state relationships among terms. A structure is also a predicate when its context specifies it to be a query (question).

16.6.2 Fact Statements

Our discussion of Prolog statements begins with those statements used to construct the hypotheses, or database of assumed information—the statements from which new information can be inferred.

Prolog has two basic statement forms; these correspond to the headless and headed Horn clauses of predicate calculus. The simplest form of headless Horn clause in Prolog is a single structure, which is interpreted as an unconditional assertion, or fact. Logically, facts are simply propositions that are assumed to be true.

The following examples illustrate the kinds of facts one can have in a Prolog program. Notice that every Prolog statement is terminated by a period.

```
female(shelley).
male(bill).
female(mary).
male(jake).
father(bill, jake).
father(bill, shelley).
```

```
mother(mary, jake).
mother(mary, shelley).
```

These simple structures state certain facts about `jake`, `shelley`, `bill`, and `mary`. For example, the first states that `shelley` is a `female`. The last four connect their two parameters with a relationship that is named in the functor atom; for example, the fifth proposition might be interpreted to mean that `bill` is the `father` of `jake`. Note that these Prolog propositions, like those of predicate calculus, have no intrinsic semantics. They mean whatever the programmer wants them to mean. For example, the proposition

```
father(bill, jake).
```

could mean `bill` and `jake` have the same `father` or that `jake` is the `father` of `bill`. The most common and straightforward meaning, however, might be that `bill` is the `father` of `jake`.

16.6.3 Rule Statements

The other basic form of Prolog statement for constructing the database corresponds to a headed Horn clause. This form can be related to a known theorem in mathematics from which a conclusion can be drawn if the set of given conditions is satisfied. The right side is the antecedent, or *if* part, and the left side is the consequent, or *then* part. If the antecedent of a Prolog statement is true, then the consequent of the statement must also be true. Because they are Horn clauses, the consequent of a Prolog statement is a single term, while the antecedent can be either a single term or a conjunction.

Conjunctions contain multiple terms that are separated by logical AND operations. In Prolog, the AND operation is implied. The structures that specify atomic propositions in a conjunction are separated by commas, so one could consider the commas to be AND operators. As an example of a conjunction, consider the following:

```
female(shelley), child(shelley).
```

The general form of the Prolog headed Horn clause statement is

```
consequence :- antecedent_expression.
```

It is read as follows: “consequence can be concluded if the antecedent expression is true or can be made to be true by some instantiation of its variables.” For example,

```
ancestor(mary, shelley) :- mother(mary, shelley).
```

states that if `mary` is the `mother` of `shelley`, then `mary` is an `ancestor` of `shelley`. Headed Horn clauses are called **rules**, because they state rules of implication between propositions.

As with clausal form propositions in predicate calculus, Prolog statements can use variables to generalize their meaning. Recall that variables in clausal form provide a kind of implied universal quantifier. The following demonstrates the use of variables in Prolog statements:

```
parent(X, Y) :- mother(X, Y).
parent(X, Y) :- father(X, Y).
grandparent(X, Z) :- parent(X, Y) , parent(Y, Z).
```

These statements give rules of implication among some variables, or universal objects. In this case, the universal objects are `X`, `Y`, and `Z`. The first rule states that if there are instantiations of `X` and `Y` such that `mother(X, Y)` is true, then for those same instantiations of `X` and `Y`, `parent(X, Y)` is true.

The `=` operator, which is an infix operator, succeeds if its two term operands are the same. For example, `X = Y`. The `not` operator, which is a unary operator, reverses its operand, in the sense that it succeeds if its operand fails. For example, `not(X = Y)` succeeds if `X` is not equal to `Y`.

16.6.4 Goal Statements

So far, we have described the Prolog statements for logical propositions, which are used to describe both known facts and rules that describe logical relationships among facts. These statements are the basis for the theorem-proving model. The theorem is in the form of a proposition that we want the system to either prove or disprove. In Prolog, these propositions are called

goals, or **queries**. The syntactic form of Prolog goal statements is identical to that of headless Horn clauses. For example, we could have

```
man(fred).
```

to which the system will respond either `yes` or `no`. The answer `yes` means that the system has proved the goal was true under the given database of facts and relationships. The answer `no` means that either the goal was determined to be false or the system was simply unable to prove it.

Conjunctive propositions and propositions with variables are also legal goals. When variables are present, the system not only asserts the validity of the goal but also identifies the instantiations of the variables that make the goal true. For example,

```
father(X, mike).
```

can be asked. The system will then attempt, through unification, to find an instantiation of `X` that results in a true value for the goal.

Because goal statements and some nongoal statements have the same form (headless Horn clauses), a Prolog implementation must have some means of distinguishing between the two. Interactive Prolog implementations do this by simply having two modes, indicated by different interactive prompts: one for entering fact and rule statements and one for entering goals. The user can change the mode at any time.

16.6.5 The Inferencing Process of Prolog

This section examines Prolog resolution. Efficient use of Prolog requires that the programmer know precisely what the Prolog system does with his or her program.

When a goal is a compound proposition, each of the facts (structures) is called a **subgoal**. To prove that a goal is true, the inferencing process must find a chain of inference rules and/or facts in the database that connect the goal to one or more facts in the database. For example, if *Q* is the goal, then either *Q* must be found as a fact in the database or the inferencing process must find a fact P1 and a sequence of propositions P2, P3…, Pn such that

- P2 : - P1
- P3 : - P2
- . . .
- *Q* : - Pn

Of course, the process can be and often is complicated by rules with compound right sides and rules with variables. The process of finding the *P*s, when they exist, is basically a comparison, or matching, of terms with each other.

Because the process of proving a subgoal is done through a proposition--matching process, it is sometimes called **matching**. In some cases, proving a subgoal is called **satisfying** that subgoal.

Consider the following query:

```
man(bob).
```

This goal statement is the simplest kind. It is relatively easy for resolution to determine whether it is true or false: The pattern of this goal is compared with the facts and rules in the database. If the database includes the fact

```
man(bob).
```

the proof is trivial. If, however, the database contains the following fact and inference rule,

```
father(bob).
man(X) :- father(X).
```

Prolog would be required to find these two statements and use them to infer the truth of the goal. This would necessitate unification to instantiate `X` temporarily to `bob`.

Now consider the goal

```
man(X).
```

In this case, Prolog must match the goal against the propositions in the database. The first proposition that it finds that has the form of the goal, with any object as its parameter, will cause `X` to be instantiated with that object's value. `X` is then displayed as the result. If there is no proposition having the form of the goal, the system indicates, by saying `no`, that the goal cannot be satisfied.

There are two opposite approaches to attempting to match a given goal to a fact in the database. The system can begin with the facts and rules of the database and attempt to find a sequence of matches that lead to the goal. This approach is called **bottom-up resolution**, or **forward chaining**. The alternative is to begin with the goal and attempt to find a sequence of matching propositions that lead to some set of original facts in the database. This approach is called **top-down resolution**, or **backward chaining**. In general, backward chaining works well when there is a reasonably small set of candidate answers. The forward chaining approach is better when the number of possibly correct answers is large; in this situation, backward chaining would require a very large number of matches to get to an answer. Prolog implementations use backward chaining for resolution, presumably

because its designers believed backward chaining was more suitable for a larger class of problems than forward chaining.

The following example illustrates the difference between forward and backward chaining. Consider the query:

```
man(bob).
```

Assume the database contains

```
father(bob).
man(X) :- father(X).
```

Forward chaining would search for and find the first proposition. The goal is then inferred by matching the first proposition with the right side of the second rule (`father(X)`) through instantiation of `X` to `bob` and then matching the left side of the second proposition to the goal. Backward chaining would first match the goal with the left side of the second proposition (`man(X)`) through the instantiation of `X` to `bob`. As its last step, it would match the right side of the second proposition (now `father(bob)`) with the first proposition.

The next design question arises whenever the goal has more than one structure, as in our example. The question then is whether the solution search is done depth first or breadth first. A **depth-first** search finds a complete sequence of propositions—a proof—for the first subgoal before working on the others. A **breadth-first** search works on all subgoals of a given goal in parallel. Prolog's designers chose the depth-first approach primarily because it can be done with fewer computer resources. The breadth-first approach is a parallel search that can require a large amount of memory.

The last feature of Prolog's resolution mechanism that must be discussed is backtracking. When a goal with multiple subgoals is being processed and the system fails to show the truth of one of the subgoals, the system abandons the subgoal it cannot prove. It then reconsiders the previous subgoal, if there is one, and attempts to find an alternative solution to it. This backing up in the goal to the reconsideration of a previously proven subgoal is called **backtracking**. A new solution is found by beginning the search where the previous search for that subgoal stopped. Multiple solutions to a subgoal result from different instantiations of its variables. Backtracking can require a

great deal of time and space because it may have to find all possible proofs to every subgoal. These subgoal proofs may not be organized to minimize the time required to find the one that will result in the final complete proof, which exacerbates the problem.

To solidify your understanding of backtracking, consider the following example. Assume that there is a set of facts and rules in the database and that Prolog has been presented with the following compound goal:

```
male(X), parent(X, shelley).
```

This goal asks whether there is an instantiation of `X` such that `X` is a `male` and `X` is a `parent` of `shelley`. As its first step, Prolog finds the first fact in the database with `male` as its functor. It then instantiates `X` to the parameter of the found fact, say `mike`. Then, it attempts to prove that `parent(mike, shelley)` is true. If it fails, it backtracks to the first subgoal, `male(X)`, and attempts to resatisfy it with some alternative instantiation of `X`. The resolution process may have to find every `male` in the database before it finds the one that is a `parent` of `shelley`. It definitely must find all `male`s to prove that the goal cannot be satisfied. Note that our example goal might be processed more efficiently if the order of the two subgoals were reversed. Then, only after resolution had found a `parent` of `shelley` would it try to match that person with the `male` subgoal. This is more efficient if `shelley` has fewer parents than there are `male`s in the database, which seems like a reasonable assumption. Section 16.7.1 discusses a method of limiting the backtracking done by a Prolog system.

Database searches in Prolog always proceed in the direction of first to last.

The following two subsections describe Prolog examples that further illustrate the resolution process.

16.6.6 Simple Arithmetic

Prolog supports integer variables and integer arithmetic. Originally, the arithmetic operators were functors, so that the sum of `7` and the variable `X` was formed with

```
+(7, X)
```

Prolog now allows a more abbreviated syntax for arithmetic with the **is** operator. This operator takes an arithmetic expression as its right operand and a variable as its left operand. All variables in the expression must already be instantiated, but the left-side variable cannot be previously instantiated. For example, in

```
A is B / 17 + C.
```

if `B` and `C` are instantiated but `A` is not, then this clause will cause `A` to be instantiated with the value of the expression. When this happens, the clause is satisfied. If either `B` or `C` is not instantiated or `A` is instantiated, the clause is not satisfied and no instantiation of `A` can take place. The semantics of an **`is`** proposition is considerably different from that of an assignment statement in an imperative language. This difference can lead to an interesting scenario. Because the **`is`** operator makes the clause in which it appears look like an assignment statement, a beginning Prolog programmer may be tempted to write a statement such as

```
Sum is Sum + Number.
```

which is never useful, or even legal, in Prolog. If `Sum` is not instantiated, the reference to it in the right side is undefined and the clause fails. If `Sum` is already instantiated, the clause fails, because the left operand cannot have a current instantiation when **`is`** is evaluated. In either case, the instantiation of `Sum` to the new value will not take place. (If the value of `Sum + Number` is required, it can be bound to some new name.)

Prolog does not have assignment statements in the same sense as imperative languages. They are simply not needed in most of the programming for which Prolog was designed. The usefulness of assignment statements in imperative languages often depends on the capability of the programmer to control the execution control flow of the code in which the assignment statement is embedded. Because this type of control is not always possible in Prolog, such statements are far less useful.

As a simple example of the use of numeric computation in Prolog, consider the following problem: Suppose we know the average speeds of several

automobiles on a particular racetrack and the amount of time they are on the track. This basic information can be coded as facts, and the relationship between speed, time, and distance can be written as a rule, as in the following:

```
speed(ford, 100).
speed(chevy, 105).
speed(dodge, 95).
speed(volvo, 80).
time(ford, 20).
time(chevy, 21).
time(dodge, 24).
time(volvo, 24).
distance(X, Y) :- speed(X, Speed),
                  time(X, Time),
                  Y is Speed * Time.
```

Now, queries can request the distance traveled by a particular car. For example, the query

```
distance(chevy, Chevy_Distance).
```

instantiates `Chevy_Distance` with the value 2205. The first two clauses in the right side of the distance computation statement instantiate the variables `Speed` and `Time` with the corresponding values of the given automobile functor. After satisfying the goal, Prolog also displays the name `Chevy_Distance` and its value.

At this point it is instructive to take an operational look at how a Prolog system produces results. Prolog has a built-in structure named `trace` that displays the instantiations of values to variables at each step during the attempt to satisfy a given goal. `trace` is used to understand and debug Prolog programs. To understand `trace`, it is best to introduce a different model of the execution of Prolog programs, called the **tracing model**.

The tracing model describes Prolog execution in terms of four events: (1) call, which occurs at the beginning of an attempt to satisfy a goal, (2) exit, which occurs when a goal has been satisfied, (3) redo, which occurs when backtrack causes an attempt to resatisfy a goal, and (4) fail, which occurs when a goal fails. Call and exit can be related directly to the execution model

of a subprogram in an imperative language if processes like `distance` are thought of as subprograms. The other two events are unique to logic programming systems. In the following trace example, a trace of the computation of the value for `Chevy_Distance`, the goal requires no redo or fail events:

```
trace.
adistance(chevy, Chevy_Distance).
(1) 1 Call: distance(chevy, _0)?
(2) 2 Call: speed(chevy, _5)?
(2) 2 Exit: speed(chevy, 105)
(3) 2 Call: time(chevy, _6)?
(3) 2 Exit: time(chevy, 21)
(4) 2 Call: _0 is 105*21?
(4) 2 Exit: 2205 is 105*21
(1) 1 Exit: distance(chevy, 2205)
Chevy_Distance = 2205
```

Symbols in the trace that begin with the underscore character (_) are internal variables used to store instantiated values. The first column of the trace indicates the subgoal whose match is currently being attempted. For example, in the example trace, the first line with the indication `(3)` is an attempt to instantiate the temporary variable `_6` with a `time` value for `chevy`, where `time` is the second term in the right side of the statement that describes the computation of `distance`. The second column indicates the call depth of the matching process. The third column indicates the current action.

To illustrate backtracking, consider the following example database and traced compound goal:

```
likes(jake, chocolate).
likes(jake, apricots).
likes(darcie, licorice).
likes(darcie, apricots).
trace.
likes(jake, X), likes(darcie, X).
(1) 1 Call: likes(jake, _0)?
(1) 1 Exit: likes(jake, chocolate)
(2) 1 Call: likes(darcie, chocolate)?
(2) 1 Fail: likes(darcie, chocolate)
(1) 1 Redo: likes(jake, _0)?
(1) 1 Exit: likes(jake, apricots)
(3) 1 Call: likes(darcie, apricots)?
```

```
(3) 1 Exit: likes(darcie, apricots)
X = apricots
```

One can think about Prolog computations graphically as follows: Consider each goal as a box with four ports—call, fail, exit, and redo. Control enters a goal in the forward direction through its call port. Control can also enter a goal from the reverse direction through its redo port. Control can also leave a goal in two ways: If the goal succeeded, control leaves through the exit port; if the goal failed, control leaves through the fail port. A model of the example is shown in Figure 16.1. In this example, control flows through each subgoal twice. The second subgoal fails the first time, which forces a return through redo to the first subgoal.

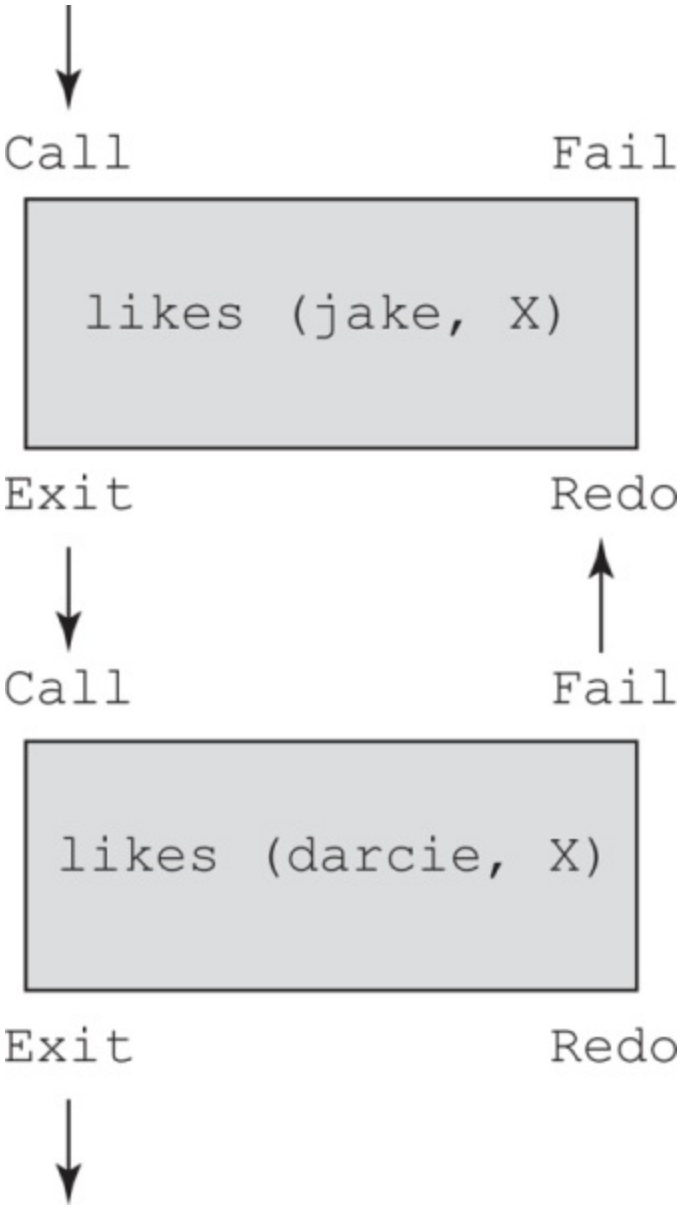

Figure 16.1 Control flow model for the goal `likes (jake, X), likes (darcie, X)`

16.6.7 List Structures

So far, the only Prolog data structure we have discussed is the atomic proposition, which looks more like a function call than a data structure. Atomic propositions, which are also called structures, are actually a form of records. The other basic data structure supported is the list. Lists are sequences of any number of elements, where the elements can be atoms, atomic propositions, or any other terms, including other lists.

Prolog uses the syntax of ML and Haskell to specify lists. The list elements are separated by commas, and the entire list is delimited by square brackets, as in

```
[apple, prune, grape, kumquat]
```

The notation `[]` is used to denote the empty list. Instead of having explicit functions for constructing and dismantling lists, Prolog simply uses a special notation. `[X | Y]` denotes a list with head `X` and tail `Y`, where head and tail correspond to `CAR` and `CDR` in LISP. This is similar to the notation used in ML and Haskell.

A list can be created with a simple structure, as in

```
new_list([apple, prune, grape, kumquat]).
```

which states that the constant list `[apple, prune, grape, kumquat]` is a new element of the relation named `new_list` (a name we just made up). This statement does not bind the list to a variable named `new_list`; rather, it does the kind of thing that the proposition

```
male(jake)
```

does. That is, it states that `[apple, prune, grape, kumquat]` is a new element of `new_list`. Therefore, we could have a second proposition with a list argument, such as

```
new_list([apricot, peach, pear])
```

In query mode, one of the elements of `new_list` can be dismantled into head and tail with

```
new_list([New_List_Head | New_List_Tail]).
```

If `new_list` has been set to have the two elements as shown, this statement instantiates `New_List_Head` with the head of the first list element (in this case, `apple`) and `New_List_Tail` with the tail of the list (or `[prune, grape, kumquat]`). If this were part of a compound goal and backtracking forced a new evaluation of it, `New_List_Head` and `New_List_Tail` would be reinstantiated to `apricot` and `[peach, pear]`, respectively, because `[apricot, peach, pear]` is the next element of `new_list`.

The `|` operator used to dismantle lists can also be used to create lists from given instantiated head and tail components, as in

```
[Element_1 | List_2]
```

If `Element_1` has been instantiated with `pickle` and `List_2` has been instantiated with `[peanut, prune, popcorn]`, the sample notation will create, for this one reference, the list `[pickle, peanut, prune, popcorn]`.

As stated previously, the list notation that includes the `|` symbol is universal: It can specify either a list construction or a list dismantling. Note further that the following are equivalent:

```
[apricot, peach, pear | []]
[apricot, peach | [pear]]
[apricot | [peach, pear]]
```

With lists, certain basic operations are often required, such as those found in LISP, ML, and Haskell. As an example of such operations in Prolog, we examine a definition of `append`, which is related to such a function in LISP. In this example, the differences and similarities between functional and declarative languages can be seen. We need not specify how Prolog is to construct a new list from the given lists; rather, we need specify only the characteristics of the new list in terms of the given lists.

In appearance, the Prolog definition of `append` is very similar to the ML

version that appears in Chapter 15, and a kind of recursion in resolution is used in a similar way to produce the new list. In the case of Prolog, the recursion is caused and controlled by the resolution process. As with ML and Haskell, a pattern-matching process is used to choose, based on the actual parameter, between two different definitions of the append process.

The first two parameters to the `append` operation in the following code are the two lists to be appended, and the third parameter is the resulting list:

```
append([], List, List).
append([Head | List_1], List_2, [Head | List_3]) :-
            append(List_1, List_2, List_3).
```

The first proposition specifies that when the empty list is appended to any other list, that other list is the result. This statement corresponds to the -recursion-terminating step of the ML `append` function. Note that the terminating proposition is placed before the recursion proposition. This is done because we know that Prolog will match the two propositions in order, starting with the first (because of its use of the depth-first order).

The second proposition specifies several characteristics of the new list. It corresponds to the recursion step in the ML function. The left-side predicate states that the first element of the new list is the same as the first element of the first given list, because they are both named `Head`. Whenever `Head` is instantiated to a value, all occurrences of `Head` in the goal are, in effect, simultaneously instantiated to that value. The right side of the second statement specifies that the tail of the first given list `(List_1)` has the second given list `(List_2)` appended to it to form the tail `(List_3)` of the resulting list.

One way to read the second statement of `append` is as follows: Appending the list `[Head | List_1]` to any list `List_2` produces the list `[Head | List_3]`, but only if the list `List_3` is formed by appending `List_1` to `List_2`. In LISP, this would be

```
(CONS (CAR FIRST) (APPEND (CDR FIRST) SECOND))
```

In both the Prolog and LISP versions, the resulting list is not constructed until the recursion produces the terminating condition; in this case, the first list

must become empty. Then, the resulting list is built using the append function itself; the elements taken from the first list are added, in reverse order, to the second list. The reversing is done by the unraveling of the recursion.

One fundamental difference between Prolog's append and those of LISP and ML is that Prolog's append is a predicate—it does not return a list, it returns yes or no. The new list is the value of its third parameter.

To illustrate how the append process progresses, consider the following traced example:

```
trace.
append([bob, jo], [jake, darcie], Family).
(1) 1 Call: append([bob, jo], [jake, darcie], _10)?
(2) 2 Call: append([jo], [jake, darcie], _18)?
(3) 3 Call: append([], [jake, darcie], _25)?
(3) 3 Exit: append([], [jake, darcie], [jake, darcie])
(2) 2 Exit: append([jo], [jake, darcie], [jo, jake,
                    darcie])
(1) 1 Exit: append([bob, jo], [jake, darcie],
                   [bob, jo, jake, darcie])
Family = [bob, jo, jake, darcie]
yes
```

The first two calls, which represent subgoals, have List_1 nonempty, so they create the recursive calls from the right side of the second statement. The left side of the second statement effectively specifies the arguments for the recursive calls, or goals, thus dismantling the first list one element per step. When the first list becomes empty, in a call, or subgoal, the current instance of the right side of the second statement succeeds by matching the first statement. The effect of this is to return as the third parameter the value of the empty list appended to the second original parameter list. On successive exits, which represent successful matches, the elements that were removed from the first list are appended to the resulting list, Family. When the exit from the first goal is accomplished, the process is complete, and the resulting list is displayed.

Another difference between Prolog's append and those of LISP and ML is that Prolog's append is more flexible than that of those languages. For example, in Prolog we can use append to determine what two lists can be

appended to get `[a, b, c]` with

```
append(X, Y, [a, b, c]).
```

This results in the following:

```
X = []
Y = [a, b, c]
```

If we type a semicolon at this output we get the alternative result:

```
X = [a]
Y = [b, c]
```

Continuing, we get the following:

```
X = [a, b]
Y = [c];
X = [a, b, c]
Y = []
```

The `append` predicate can also be used to create other list operations, such as the following, whose effect we invite the reader to determine. Note that `list_op_2` is meant to be used by providing a list as its first parameter and a variable as its second, and the result of `list_op_2` is the value to which the second parameter is instantiated.

```
list_op_2([], []).
list_op_2([Head | Tail], List) :-
list_op_2(Tail, Result), append(Result, [Head], List).
```

As you may have been able to determine, `list_op_2` causes the Prolog system to instantiate its second parameter with a list that has the elements of the list of the first parameter, but in reverse order. For example, `([apple, orange, grape], Q)` instantiates `Q` with the list `[grape, orange, apple]`.

Once again, although the LISP and Prolog languages are fundamentally different, similar operations can use similar approaches. In the case of the reverse operation, both the Prolog's `list_op_2` and LISP's `reverse` function include the recursion-terminating condition, along with the basic process of appending the reversal of the `CDR` or tail of the list to the `CAR` or head of the

list to create the result list.

The following is a trace of this process, now named `reverse`:

```
trace.
reverse([a, b, c], Q).
(1) 1 Call: reverse([a, b, c], _6)?
(2) 2 Call: reverse([b, c], _65636)?
(3) 3 Call: reverse([c], _65646)?
(4) 4 Call: reverse([], _65656)?
(4) 4 Exit: reverse([], [])
(5) 4 Call: append([], [c], _65646)?
(5) 4 Exit: append([], [c], [c])
(3) 3 Exit: reverse([c], [c])
(6) 3 Call: append([c], [b], _65636)?
(7) 4 Call: append([], [b], _25)?
(7) 4 Exit: append([], [b], [b])
(6) 3 Exit: append([c], [b], [c, b])
(2) 2 Exit: reverse([b, c], [c, b])
(8) 2 Call: append([c, b], [a], _6)?
(9) 3 Call: append([b], [a], _32)?
(10) 4 Call: append([], [a], _39)?
(10) 4 Exit: append([], [a], [a])
(9) 3 Exit: append([b], [a], [b, a])
(8) 2 Exit: append([c, b], [a], [c, b, a])
(1) 1 Exit: reverse([a, b, c], [c, b, a])
Q = [c, b, a]
```

Suppose we need to be able to determine whether a given symbol is in a given list. A straightforward Prolog description of this is

```
member(Element, [Element | _]).
member(Element, [_ | List]) :- member(Element, List).
```

The underscore indicates an “anonymous” variable; it is used to mean that we do not care what instantiation it might get from unification. The first `-` statement in the previous example succeeds if `Element` is the head of the list, either initially or after several recursions through the second statement. The second statement succeeds if `Element` is in the tail of the list. Consider the `-` following traced examples:

```
trace.
member(a, [b, c, d]).
(1) 1 Call: member(a, [b, c, d])?
```

```
(2) 2 Call: member(a, [c, d])?
(3) 3 Call: member(a, [d])?
(4) 4 Call: member(a, [])?
(4) 4 Fail: member(a, [])
(3) 3 Fail: member(a, [d])
(2) 2 Fail: member(a, [c, d])
(1) 1 Fail: member(a, [b, c, d])
no
member(a, [b, a, c]).
(1) 1 Call: member(a, [b, a, c])?
(2) 2 Call: member(a, [a, c])?
(2) 2 Exit: member(a, [a, c])
(1) 1 Exit: member(a, [b, a, c])
yes
```

16.7 Deficiencies of Prolog

Although Prolog is a useful tool, it is neither a pure nor a perfect logic programming language. This section describes some of the problems with Prolog.

16.7.1 Resolution Order Control

Prolog, for reasons of efficiency, allows the user to control the ordering of - pattern matching during resolution. In a pure logic programming environment, the order of attempted matches that take place during resolution is nondeterministic, and all matches could be attempted concurrently. However, because Prolog always matches in the same order, starting at the beginning of the database and at the left end of a given goal, the user can profoundly affect efficiency by ordering the database statements to optimize a particular application. For example, if the user knows that certain rules are much more likely to succeed than the others during a particular "execution," then the program can be made more efficient by placing those rules at the beginning of the database.

In addition to allowing the user to control database and subgoal ordering, Prolog, in another concession to efficiency, allows some explicit control of backtracking. This is done with the cut operator, which is specified by an exclamation point (`!`). The cut operator is actually a goal, not an operator. As a goal, it always succeeds immediately, but it cannot be resatisfied through backtracking. Thus, a side effect of the cut is that subgoals to its left in a compound goal also cannot be resatisfied through backtracking. For example, in the goal

```
a, b, !, c, d.
```

if both `a` and `b` succeed but `c` fails, the whole goal fails. This goal would be used if it were known that whenever `c` fails, it is a waste of time to resatisfy `b` or `a`.

The purpose of the cut then is to allow the user to make programs more efficient by telling the system when it should not attempt to resatisfy subgoals that presumably could not result in a complete proof.

As an example of the use of the cut operator, consider the `member` rules from Section 16.6.7, which are:

```
member(Element, [Element | _]).
member(Element, [_ | List]) :- member(Element, List).
```

If the list argument to `member` represents a set, then it can be satisfied only once (sets contain no duplicate elements). Therefore, if `member` is used as a subgoal in a multiple subgoal goal statement, there can be a problem. The problem is that if `member` succeeds but the next subgoal fails, backtracking will attempt to resatisfy `member` by continuing a prior match. But because the list argument to `member` has only one copy of the element to begin with, `member` cannot possibly succeed again, which eventually causes the whole goal to fail, in spite of any additional attempts to resatisfy `member`. For example, consider the goal:

```
dem_candidate(X) :- member(X, democrats), tests(X).
```

This goal determines whether a given person is a democrat and is a good candidate to run for a particular position. The `tests` subgoal checks a variety of characteristics of the given democrat to determine the suitability of the person for the position. If the set of democrats has no duplicates, then we do not want to back up to the `member` subgoal if the `tests` subgoal fails, because `member` will search all of the other democrats but fail, because there are no duplicates. The second attempt of `member` subgoal will be a waste of computation time. The solution to this inefficiency is to add a right side to the first statement of the `member` definition, with the cut operator as the sole element, as in

```
member(Element, [Element | _]) :- !.
```

Backtracking will not attempt to resatisfy `member` but instead will cause the entire subgoal to fail.

Cut is particularly useful in a programming strategy in Prolog called

generate and test. In programs that use the generate-and-test strategy, the goal consists of subgoals that generate potential solutions, which are then checked by later "test" subgoals. Rejected solutions require backtracking to "generator" subgoals, which generate new potential solutions. As an example of a generate-and-test program, consider the following, which appears in Clocksin and Mellish (2013):

```
divide(N1, N2, Result) :- is_integer(Result),
        Product1 is Result * N2,
        Product2 is (Result + 1) * N2,
        Product1 =< N1, Product2 >
          N1, !.
```

This program performs integer division, using addition and multiplication. Because most Prolog systems provide division as an operator, this program actually is not useful, other than to illustrate a simple generate-and-test program.

The predicate `is_integer` succeeds as long as its parameter can be instantiated to some nonnegative integer. If its argument is not instantiated, `is_integer` instantiates it to the value 0. If the argument is instantiated to an integer, `is_integer` instantiates it to the next larger integer value.

So, in `divide`, `is_integer` is the generator subgoal. It generates elements of the sequence 0, 1, 2, . . . , one each time it is satisfied. All of the other subgoals are the testing subgoals—they check to determine whether the value produced by `is_integer` is, in fact, the quotient of the first two parameters, `N1` and `N2`. The purpose of the cut as the last subgoal is simple: It prevents `divide` from ever trying to find an alternative solution once it has found *the* solution. Although `is_integer` can generate a huge number of candidates, only one is the solution, so the cut here prevents useless attempts to produce secondary solutions.

Use of the cut operator has been compared to the use of the goto in imperative languages (van Emden, 1980). Although it is sometimes needed, it is possible to abuse it. Indeed, it is sometimes used to make logic programs have a control flow that is inspired by imperative programming styles.

The ability to tamper with control flow in a Prolog program is a deficiency,

because it is directly detrimental to one of the important advantages of logic programming—that programs do not specify how solutions are to be found. Rather, they simply specify what the solution should look like. This design makes programs easier to write and easier to read. They are not cluttered with the details of how the solutions are to be determined and, in particular, the precise order in which the computations are done to produce the solution. So, while logic programming requires no control flow directions, Prolog programs frequently use them, mostly for the sake of efficiency.

16.7.2 The Closed-World Assumption

The nature of Prolog's resolution sometimes creates misleading results. The only truths, as far as Prolog is concerned, are those that can be proved using its database. It has no knowledge of the world other than its database. When the system receives a query and the database does not have information to prove the query absolutely, the query is assumed to be false. Prolog can prove that a given goal is true, but it cannot prove that a given goal is false. It simply assumes that, because it cannot prove a goal true, the goal must be false. In essence, Prolog is a true/fail system, rather than a true/false system.

Actually, the closed-world assumption should not be at all foreign to you—our judicial system operates the same way. Suspects are innocent until proven guilty. They need not be proven innocent. If a trial cannot prove a person guilty, he or she is considered innocent.

The problem of the closed-world assumption is related to the negation problem, which is discussed in the following subsection.

16.7.3 The Negation Problem

Another problem with Prolog is its difficulty with negation. Consider the following database of two facts and a relationship:

```
parent(bill, jake).
parent(bill, shelley).
sibling(X, Y) :- (parent(M, X), parent(M, Y).
```

Now, suppose we typed the query

```
sibling(X, Y).
```

Prolog will respond with

```
X = jake
Y = jake
```

Thus, Prolog "thinks" `jake` is a `sibling` of himself. This happens because the system first instantiates `M` with `bill` and `X` with `jake` to make the first subgoal, `parent(M, X)`, true. It then starts at the beginning of the database again to match the second subgoal, `parent(M, Y)`, and arrives at the instantiations of `M` with `bill` and `Y` with `jake`. Because the two subgoals are satisfied independently, with both matchings starting at the database's beginning, the shown response appears. To avoid this result, `X` must be specified to be a `sibling` of `Y` only if they have the same `parents` *and* they are not the same. Unfortunately, stating that they are not equal is not straightforward in Prolog, as we will discuss. The most exacting method would require adding a fact for every pair of atoms, stating that they were not the same. This can, of course, cause the database to become very large, for there is often far more negative information than positive information. For example, most people have 364 more unbirthdays than they have birthdays.

A simple alternative solution is to state in the goal that `X` must not be the same as `Y`, as in

```
sibling(X, Y) :- parent(M, X), parent(M, Y), not(X = Y).
```

In other situations, the solution is not so simple.

The Prolog `not` operator is satisfied in this case if resolution cannot satisfy the subgoal `X = Y`. Therefore, if the `not` succeeds, it does not necessarily mean that `X` is not equal to `Y`; rather, it means that resolution cannot prove from the database that `X` is the same as `Y`. Thus, the Prolog `not` operator is not equivalent to a logical NOT operator, in which NOT means that its operand is

probably true. This nonequivalency can lead to a problem if we happen to have a goal of the form

```
not(not(some_goal)).
```

which would be equivalent to

```
some_goal.
```

if Prolog's `not` operator were a true logical NOT operator. In some cases, however, they are not the same. For example, consider again the `member` rules:

```
member(Element, [Element | _]) :- !.
member(Element, [_ | List]) :- member(Element, List).
```

To discover one of the elements of a given list, we could use the goal

```
member(X, [mary, fred, barb]).
```

which would cause `X` to be instantiated with `mary`, which would then be printed. But if we used

```
not(not(member(X, [mary, fred, barb]))).
```

the following sequence of events would take place: First, the inner goal would succeed, instantiating `X` to `mary`. Then, Prolog would attempt to satisfy the next goal:

```
not(member(X, [mary, fred, barb])).
```

This statement would fail because `member` succeeded. When this goal failed, `X` would be uninstantiated, because Prolog always uninstantiates all variables in all goals that fail. Next, Prolog would attempt to satisfy the outer `not` goal, which would succeed, because its argument had failed. Finally, the result, which is `X`, would be printed. But `X` would not be currently instantiated, so the system would indicate that. Generally, uninstantiated variables are printed in the form of a string of digits preceded by an underscore. So, the fact that Prolog's `not` is not equivalent to a logical NOT can be, at the very least, misleading.

The fundamental reason why logical NOT cannot be an integral part of Prolog is the form of the Horn clause:

- A :- $B_1 \cap B_2 \cap \ldots \cap B_n$

If all the B propositions are true, it can be concluded that A is true. But regardless of the truth or falseness of any or all of the B's, it cannot be concluded that A is false. From positive logic, one can conclude only positive logic. Thus, the use of Horn clause form prevents any negative conclusions.

16.7.4 Intrinsic Limitations

A fundamental goal of logic programming, as stated in Section 16.4, is to provide nonprocedural programming; that is, a system by which programmers specify what a program is supposed to do but need not specify how that is to be accomplished. The example given there for sorting is rewritten here:

- sort(old_list, new_list) $\subset$ permute(old_list, new_list) $\cap$ sorted(new_list)
- sorted(list) $\subset \forall$ j such that $1 \leq j < n$, list(j) $\leq$ list (j+1)

It is straightforward to write this in Prolog. For example, the sorted subgoal can be expressed as

```
sorted ([]).
sorted ([x]).
sorted ([x, y | list]) :- x <= y, sorted ([y | list]).
```

The problem with this sort process is that it has no idea of how to sort, other than simply to enumerate all permutations of the given list until it happens to create the one that has the list in sorted order—a very slow process, indeed.

So far, no one has discovered a process by which the description of a sorted list can be transformed into some efficient algorithm for sorting. Resolution is capable of many interesting things, but certainly not this. Therefore, a Prolog program that sorts a list must specify the details of how that sorting

can be done, as is the case in an imperative or functional language.

Do all of these problems mean that logic programming should be abandoned? Absolutely not! As it is, it is capable of dealing with many useful applications. Furthermore, it is based on an intriguing concept and is therefore interesting in and of itself. Finally, there is the possibility that new inferencing techniques will be developed that will allow a logic programming language system to efficiently deal with progressively larger classes of problems.

16.8 Applications of Logic Programming

In this section, we briefly describe a few of the larger classes of present and potential applications of logic programming in general and Prolog in particular.

16.8.1 Relational Database Management Systems

Relational database management systems (RDBMSs) store data in the form of tables. Queries on such databases are often stated in Structured Query Language (SQL). SQL is nonprocedural in the same sense that logic programming is nonprocedural. The user does not describe how to retrieve the answer; rather, he or she describes only the characteristics of the answer. The connection between logic programming and RDBMSs should be obvious. Simple tables of information can be described by Prolog structures, and relationships between tables can be conveniently and easily described by Prolog rules. The retrieval process is inherent in the resolution operation. The goal statements of Prolog provide the queries for the RDBMS. Logic programming is thus a natural match to the needs of implementing an RDBMS.

One of the advantages of using logic programming to implement an RDBMS is that only a single language is required. In a typical RDBMS, a database language includes statements for data definitions, data manipulation, and queries, all of which are embedded in a general-purpose programming language, such as COBOL. The general-purpose language is used for processing the data and input and output functions. All of these functions can be done in a logic programming language.

Another advantage of using logic programming to implement an RDBMS is that deductive capability is built in. Conventional RDBMSs cannot deduce anything from a database other than what is explicitly stored in them. They contain only facts, rather than facts *and* inference rules. The primary disadvantage of using logic programming for an RDBMS, compared with a conventional RDBMS, is that the logic programming implementation is slower. Logical inferences take longer than ordinary table look-up methods using imperative programming techniques.

16.8.2 Expert Systems

Expert systems are computer systems designed to emulate human expertise in some particular domain. They consist of a database of facts, an inferencing process, some heuristics about the domain, and some friendly human interface that makes the system appear much like an expert human consultant. In addition to their initial knowledge base, which is provided by a human expert, expert systems learn from the process of being used, so their databases must be capable of growing dynamically. Also, an expert system should include the capability of interrogating the user to get additional information when it determines that such information is needed.

One of the central problems for the designer of an expert system is dealing with the inevitable inconsistencies and incompleteness of the database. Logic programming appears to be well suited to deal with these problems. For example, default inference rules can help deal with the problem of incompleteness.

Prolog can and has been used to construct expert systems. It can easily fulfill the basic needs of expert systems, using resolution as the basis for query processing, using its ability to add facts and rules to provide the learning capability, and using its trace facility to inform the user of the “reasoning” behind a given result. Missing from Prolog is the automatic ability of the system to query the user for additional information when it is needed.

One of the most widely known uses of logic programming in expert systems is the expert system construction system known as APES, which is described

in Sergot (1983) and Hammond (1983). The APES system includes a very flexible facility for gathering information from the user during expert system construction. It also includes a second interpreter for producing explanations to its answers to queries.

APES has been successfully used to produce several expert systems, including one for the rules of a government social benefits program and one for the British Nationality Act, which is the definitive source for rules of British citizenship.

16.8.3 Natural-Language Processing

Certain kinds of natural-language processing can be done with logic programming. In particular, natural-language interfaces to computer software systems, such as intelligent databases and other intelligent knowledge-based systems, can be conveniently done with logic programming. For describing language syntax, forms of logic programming have been found to be equivalent to context-free grammars. Proof procedures in logic programming systems have been found to be equivalent to certain parsing strategies. In fact, backward-chaining resolution can be used directly to parse sentences whose structures are described by context-free grammars. It has also been discovered that some kinds of semantics of natural languages can be made clear by modeling the languages with logic programming. In particular, research in logic-based semantics networks has shown that sets of sentences in natural languages can be expressed in clausal form (Deliyanni and Kowalski, 1979). Kowalski (1979) also discusses logic-based semantic networks.

SUMMARY

Symbolic logic provides the basis for logic programming and logic programming languages. The approach of logic programming is to use as a database a collection of facts and rules that state relationships between facts and to use an automatic inferencing process to check the validity of new propositions, assuming the facts and rules of the database are true. This approach is the one developed for automatic theorem proving.

Prolog is the most widely used logic programming language. The origins of logic programming lie in Robinson's development of the resolution rule for logical inference. Prolog was developed primarily by Colmeraeur and Roussel at Marseille, with some help from Kowalski at Edinburgh.

Logic programs are nonprocedural, which means that the characteristics of the solution are given but the process of getting the solution is not.

Prolog statements are facts, rules, or goals. Most are made up of structures, which are atomic propositions, and logic operators, although arithmetic expressions are also allowed.

Resolution is the primary activity of a Prolog interpreter. This process, which uses backtracking extensively, involves mainly pattern matching among propositions. When variables are involved, they can be instantiated to values to provide matches. This instantiation process is called *unification*.

There are a number of problems with the current state of logic programming. For reasons of efficiency, and even to avoid infinite loops, programmers must sometimes state control flow information in their programs. Also, there are the problems of the closed-world assumption and negation.

Logic programming has been used in a number of different areas, primarily in relational database systems, expert systems, and natural-language processing.

BIBLIOGRAPHIC NOTES

- The Prolog language is described in several books. Edinburgh's form of the language is covered in Clocksin and Mellish (2003). The microcomputer implementation is described in Clark and McCabe (1984).

- Hogger (1991) is an excellent book on the general topic of logic programming. It is the source of the material in this chapter's section on logic programming applications.

REVIEW QUESTIONS

1. What are the three primary uses of symbolic logic in formal logic?
2. What are the two parts of a compound term?
3. What are the two modes in which a proposition can be stated?
4. What is the general form of a proposition in clausal form?
5. What are antecedents? Consequences?
6. Give general (not rigorous) definitions of *resolution* and *unification*.
7. What are the forms of Horn clauses?
8. What is the basic concept of declarative semantics?
9. What does it mean for a language to be nonprocedural?
10. What are the three forms of a Prolog term?
11. What is an uninstantiated variable?
12. What are the syntactic forms and usage of fact and rule statements in Prolog?
13. What is a conjunction?
14. Explain the two approaches to matching goals to facts in a database.
15. Explain the difference between a depth-first and a breadth-first search when discussing how multiple goals are satisfied.
16. Explain how backtracking works in Prolog.
17. Explain what is wrong with the Prolog statement `K is K + 1`.

18. What are the two ways a Prolog programmer can control the order of pattern matching during resolution?

19. Explain the generate-and-test programming strategy in Prolog.

20. Explain the closed-world assumption used by Prolog. Why is this a limitation?

21. Explain the negation problem with Prolog. Why is this a limitation?

22. Explain the connection between automatic theorem proving and Prolog's inferencing process.

23. Explain the difference between procedural and nonprocedural languages.

24. Explain why Prolog systems must do backtracking.

25. What is the relationship between resolution and unification in Prolog?

PROBLEM SET

1. Compare the concept of data typing in C# with that of Prolog.

2. Describe how a multiple-processor machine could be used to implement resolution. Could Prolog, as currently defined, use this method?

3. Write a Prolog description of your family tree (based only on facts), going back to your grandparents and including all descendants. Be sure to include all relationships.

4. Write a set of rules for family relationships, including all relationships from grandparents through two generations. Now add these to the facts of Problem 3, and eliminate as many of the facts as you can.

5. Write the following English conditional statements as Prolog-headed Horn clauses:

    1. If Fred is the father of Mike, then Fred is an ancestor of Mike.

    2. If Mike is the father of Joe and Mike is the father of Mary, then Mary is the sister of Joe.

    3. If Mike is the brother of Fred and Fred is the father of Mary, then Mike is the uncle of Mary.

6. Explain two ways in which the list-processing capabilities of Scheme and Prolog are similar.

7. In what way are the list-processing capabilities of Scheme and Prolog different?

8. Write a comparison of Prolog with ML, including two similarities and two differences.

9. From a book on Prolog, learn and write a description of an occur-check

problem. Why does Prolog allow this problem to exist in its implementation?

10. Find a good source of information on Skolem normal form and write a brief but clear explanation of it.

PROGRAMMING EXERCISES

1. Using the structures `parent(X, Y)`, `male(X)`, and `female(X)`, write a structure that defines `mother(X, Y)`.

2. Using the structures `parent(X, Y)`, `male(X)`, and `female(X)`, write a structure that defines `sister(X, Y)`.

3. Write a Prolog program that finds the maximum of a list of numbers.

4. Write a Prolog program that succeeds if the intersection of two given list parameters is empty.

5. Write a Prolog program that returns a list containing the union of the elements of two given lists.

6. Write a Prolog program that returns the final element of a given list.

7. Write a Prolog program that implements quicksort.

The architecture consists of two units, the memory unit and the central processing unit. The central processing consists of the Arithmetic and logic unit and the control unit. The control unit sends information to the arthmetic and logic unit. The input and output devices are connected to this unit. The result of the operations in the C P U is given as input to the memory unit. This unit stores both instructions and data and passes on the output to the C P U.

The first layer is the bare machine. The second layer is the macro instruction. The third layer is the operating system. The fourth layer is divided into 8 sections: A d a compiler labeled virtual a d a computer; Java virtual machine labeled virtual java computer; C compiler labeled virtual C computer; dot NET common language run time; Scheme interpreter labeled virtual scheme computer; operating system command interpreter; assembler labeled virtual assembly language computer; and an incomplete section which indicates additional items in this layer. The fifth incomplete layer includes; the java virtual computer consists of the java compiler and java compiler; the dot NET common language run time unit consists of V B dot NET compiler which is in a virtual v b dot net computer and C hash compiler labeled Virtual C hash computer.

The source program is fed into the lexical analyzer. These lexical units are passed to the syntax analyzer. The lexical analyzer and the syntax analyzer are also given as input to the symbol table. The parse trees from the syntax analyzer and the output from the symbol table is fed into the intermediate code generator and semantic analyzer. The output of this semantic analyzer is sent for optional optimization and passed to the code generator. The intermediate code generated and the output from the symbol table is given to the code generator. The code machine language generated by the code generator and input data are given to the computer which produces the results.

The source program is fed into the lexical analyzer. These lexical units are passed to the syntax analyzer. The parse trees from the analyzer are fed into the intermediate code generator. The intermediate code and input data are passed into the interpreter. The output from the interpreter is the result.

In 19 57, Fortran 1 was created which lead to the frotran continuations as well as inspiring the ALGOL programing. In 19 58, Fortran 2 was created which lead to FORTRAN 4 in 1962. In 1978, Fortran 77. In 19 90 Fortran 90. In 19 95 Fortran 95. In 2003 Fortran 2003. In 2008 Fortran 2008. In 20 15 Fortran 2015.In 19 58, ALGOL 58 was inspired by Fortran 1. And continued in it's series in 1960 with ALGOL 60. In 1966, ALGOL W which developed into pascal in 19 71, pascal in turn inspired 3 products, MODULA 2, M L, and Ada 83. On a different branch in 1968: ALGOL 68 was developed from ALGOL 60. C was partially inspired by ALGOL 68 in 19 71. ALGOL 60 inspired Basic in 19 64 which lead to quick basic in 19 88 then visual basic in 19 90 and finally visual basic dot NET in 2001. From Pascal in 19 71 there are 3 product lines, MODULA 2, M L, and Ada 83. MODULA 2 lead to oberon in 19 88. Modula 2 lead to Modula 3 in 19 88, Modela 3 partially inspired python in 19 92. In 1963, SIMULA 1 was created, inspired by ALGOL 60. In 1967, SIMULA 67. In 19 80 small talk 80. Small talk partially inspired both objective c in 19 84,which lead to swift in 20 14, and ruby in 19 94. Simula 67 along with Ada 83 both inspried Eiffel in 19 90. In 19 57 Flow matic was created which lead to COBOL in 19 60 then P L slash I in 19 64. In 19 62 C P L was created and lead to B C P L in 19 69. In 19 70 B was created which lead to C in 19 71. The line then splits into two branches. The first branch starts with A N S I, C or C 89 in 19 89 and goes on to Python in 19 91 then python 2 point 0 in 2000 and Python 3 point 0 in 2007. A N S I, C also leads to C 99 in 19 99. The second branch from C goes to C + + and Java in 19 94. Java lead to Java 5 point 0 2004, Java 6 point 0 in 2006, Java 7 point 0 in 2009, and Java 8 point 0 in 20 14. C + + also leads to C hash 2000 then to C hash 2 point 0 in 2006, C hash 3 point 0 in 2007, C hash 4 point 0 in 2009, C hash 5 point 0 in 20 12. In 19 59 L I S P was created. L I SP then inpired two product lines Scheme and M L. Scheme was made in 1975 and lead to commmon l i s p. M L was created in 19 78 an dlead to Miranda in 19 83 then Haskell 19 88. In 19 63 SNOBOL was created which lead to Icon in 19 82. Snowbol also lead to a w k in 19 78 with lead to Perl in 19 86. Pearl lead to P H P in 19 94 and Javascript in 19 96. Pearl also lead to Ruby in 19 94. Ruby lead to Ruby 1.8 in 2004 which lead to Ruby 1.9 in 2009.

The internal representation of the list A, B, C, D: A pointer points to the head node in the list. Four nodes with data parts A, B, C, and D and the next pointer linked to its successor. The node D does not have a successor and the pointer value is null. The internal representation of the list A, B, C, D, E, F, G: A pointer points to the head node A in the list. Node A is linked to Node B. Node B is linked to node D and Node C. The node C does not have a successor and the pointer value is null. Node D points to a dummy node for E with a null value. This node points to the node E which similarly points to a null node and points to Node F. This node F points to node G. The node G does not have a successor and the pointer value is null.

The first level, assign, has 3 branches from left to right, i d which represents A, equals, expression. The second level, expression, has 3 branches from left to right, i d which represents B, asterisk, expression. The third level, expression, has 3 branches from left to right, left parenthesis, expression, right parenthesis. The fourth level, i d, which represents A, plus, expression. This expression denotes the i d which represents C.

The first tree has 3 levels. The first level, assign, has 3 branches from left to right, i d which represents A, equals, expression. The second level, expression, has 3 branches from left to right, expression which represents the i d with attribute B, asterisk, and expression. The third level, expression, has 3 branches from left to right, expression, which represents the i d with attribute C, asterisk, expression, which represents the i d with attribute A. Similarly the second tree has 3 levels. The first level, assign, has 3 branches from left to right, i d which represents A, equals, expression. The second level, expression, has 3 branches from left to right, expression, asterisk, expression which represents the i d with attribute A. The third level, expression, has 3 branches from left to right, expression, which represents the i d with attribute B, +, expression, which represents the i d with attribute C.

The first level, assign, has 3 branches from left to right, i d which represents A, equals, expression. The second level, expression, has 3 branches from left to right, expression which which leads to the term and factor of i d with attribute B; plus; term. The third level, term, has 3 branches from left to right, term, which leads to the factor of i d with attribute C. the i d with attribute C; asterisk; factor of i d with attribute A.

The first level, assign, has 3 branches from left to right, i d which represents A, equals, expression. The second level, expression, has 3 branches from left to right; plus; term which leads to the factor of i d with attribute A. The third level, expression, has 3 branches from left to right, expression which which leads to the term and factor of i d with attribute B; plus; term, which leads to the factor of i d with attribute C.

First parse tree. The if statement in the first level can be expressed using 5 branches in the second level such as if, logic expression, statement, else, statement. The if statement has another if statement branch in level three which has 3 branches in the fourth level such as if, logic expression, statement. Second parse tree. The if statement in the first level can be expressed using 3 branches in the second level such as if, logic expression, statement. The statement has another if statement branch in level three and has 5 branches in the fourth level such as if, logic expression, statement, else, statement.

The first level, assign, has 3 branches to the second level, from left to right, variable with attribute A; equals; expression. This Expression has 3 branches to the third level, from left to right, variable 2 with attribute A, +, variable 3 with attribute B.

The first level, assign, has 3 branches to the second level, from left to right, variable with attribute A; equals; expression. This Expression has 3 branches to the third level, from left to right, variable 2 with attribute A, +, variable 3 with attribute B. The attribute A flows from the actual type to the expected type. The attributes A and B flow from the actual type towards the expression.

The first level, assign, has 3 branches to the second level, from left to right, variable with attribute A; equals; expression. A note beside variable reads actual type = real type. This Expression has 3 branches to the third level, from left to right, variable 2 with attribute A, +, variable 3 with attribute B. A note beside expression reads expected type = real type, actual type = real type. Notes beside variable 2 and variable 3 reads, actual type = real type and actual type = integer type.

The first level binary underscore number has two branches to the second level, bit 0 and binary number. Binary number has two branches to the third level, bit 1 and binary number. Binary number has a branch bit 1 in the fourth level.

The first level binary underscore number has two branches to the second level, bit 0 and binary number. The object 6 is attached to the first level. Binary number has two branches to the third level, bit 1 and binary number. The object 3 is attached to the second level. Binary number has a branch bit 1 in the fourth level. The object 1 is attached to the third level.

The transitions and their transitional behavior are as follows: Start to i d, Letter, add c h a r, get c h a r; Start to i n t, Digit, add c h a r, get c h a r; unknown to done, t points to look up next c h a r, get c h a r. The state i d has a self transition and its behavior reads, letter or digit, add c h a r, get c h a r. The state i n t has a self transition and its behavior reads, digit, add c h a r, get c h a r. A transition from i d reads return lookup left parenthesis lexeme right parenthesis. A transition from i n t reads, return i n t underscore l i t. Similarly a transition from done state reads, return t.

The first level, expression leads to the second level, term. Term has 3 branches to the third level, from left to right, factor, slash, factor which leads to total. The first Factor has 3 branches to the fourth level, from left to right, left parenthesis, expression and right parenthesis. Expression has three branches from left to right, term to factor to sum, +, term to factor to 47.

L R parser has two components Parser code and parser table. The parser code is connected to the parser stack and the parsing table is connected to the input. The parse stack contains the following elements: S sub 0, X sub 1, S sub 1, incomplete list, X sub m, S sub m. A pointer labeled top points towards S sub m. The input coming from parsing table consists of the following elements a sub i, a sub i + 1, blank, incomplete list, a sub n and dollar sign.

state	action, i d	action, +	action, asterisk	action, left parenthesis	action, right parenthesis	action, dollar sign	go to, E	go to, T	go to, F

The single precision format is represented using a 1 by 3 grid where the grids represent the following: sign bit, exponent in 8 bits and fraction in 23 bits.
The double precision format is represented using a 1 by 3 where the grids represent the following: sign bit, exponent in 11 bits and fraction in 52 bits.

The column values of the matrix table are: 0, 1, incomplete, j minus 1, j, incomplete, n minus 1. The row values of the matrix table are: 0, 1, incomplete, i minus 1, i, incomplete, m minus 1. The location of i, j is the cell where the column j and row i meet and is marked using a circle with a x in it.

The fields read: record, name, type, incomplete, , name, type, offset and address. There are two sets called field one and field n. Field 1 includes name, type, and offset. Field n includes name, type, and offset.

The p t r pointer with value 7080 points to the block with reference address 7080. This address block holds the value 206. A note beside this block reads an anonymous dynamic variable. This block points towards the j block and the value 206 is assigned to j.

A pointer from block r points towards action 1. Action 1 leads to action 2 and 7. Action 2 leads to action 3 and 6. Action 3 leads to action 4 and 5. Action 7 leads to action 8 and 10. Action 8 leads to action 9 and action 10 lead to actions 11 and 12.The order of the node marking is represented by creating an outline around the actions using dashed lines with an x at each step.

The value of the caller is sub left parenthesis a, b, c right parenthesis and the value of callee is void sub left parenthesis i n t, x, i n t, y, i n t z right parenthesis. The first semantic model displays the caller parameter a, being passed to the callee parameter x, the arrow is labeled call. This is an in mode transmission. The second semantic model displays the callee parameter y being returned to the caller parameter b, the arrow is labeled return. This is an out mode transmission. The third semantic model displays the caller parameter c being passed to the callee parameter z, the arrow is labeled call and the callee parameter z passed back to the caller parameter c, the arrow is labeled return. This is an in out mode transmission.

Three stacks main, stack and function sub with the following stack values: main, w, x, y, z and code; stack, value of a, value of b, value of c and address d; function sub, r e f to a, assign to b, r e f to c, assign to c and r e f to d; This is together grouped as code. The stack operations for the parameter passing methods are as follows: The main stack values w and y are passed to the stack value of a, and value of c. The address of at start is passed to the address d which is returned back to the main stack. The value of b and value of c are returned back to the main stack values x and y. The function sub parameters r e f to a, assign to b, r e f to c, assign to c and r e f to d are passed on to the stack values value of a, value of b, value of c, value of c and address of d respectively.

Illustration a. Two routines A and B where A receives the input, resume, from master. The routine A consists of sequences, resume B and routine B consists of sequences, resume A. The control transfers from resume B to resume A and back from resume A to resume B. The sequence continues.
Illustration b. Two routines A and B where B receives the input, resume, from master. The routine A consists of sequences, resume B and routine B consists of sequences, resume A. The control transfers from resume B to resume A and back from resume A to resume B. The sequence continues.

Two routines A and B where A receives the input, resume, from master. The routine A consists of sequences, resume B and routine B consists of sequences, resume A. The control transfers from resume B to resume A and back from resume A to resume B. The sequences loop back to the first sequence when it gets completed. The control from resume B to resume A is the first resume and the subsequent resume is the control from resume A to resume B.

Data has 1 cell stack in the main sub section and three cell stacks each in the lettered sections. The main section information reads local variables. Section A reads local variables, parameters, and return address. Section B reads local variables, parameters, and return address. Section C reads local variables, parameters, and return address.

From top to bottom, next to the first step reads sum. Next to the second step reads list 4. Next to the third step reads step 3. Next to the fourth step reads step 2. Next to the fifth step reads step 1. Next to the sixth step reads step 0. Next to the seventh step reads part. Next to the eighth step reads total.

At point one there are 2 sections, A R I which means activation record instance for fun 1 and A R I for main. There are 5 cell stacks in fun 1 reading, local, local, parameter, dynamic link and return to main. There is one cell stack in main which reads local. There are variables notated beside the stacks. Next to the top level is t, next to the second level is s, and next to the third level is r. The main section is labeled with variable p. A line runs from dynamic link to the bottom of the main section or sixth step. At point 2 there are 3 sections, A R I for fun 2, A R I for fun 1, and A R I for main. There are 4 cell stacks in fun 2 which read, local, parameter, dynamic link, return to fun 1. There are 5 cell stacks in fun 1 which read, local, local, parameter, dynamic link and return to main. There is one cell stack in main which reads local. There are variables notated beside the stacks. Next to the top level is y and the one below it x. The fifth level variable is t. Next to the sixth level is s, and next to the seventh level is r. Next to the bottom or tenth level is p. Two lines run from both the third line to the top of the main or bottom level and from the eighth level to the bottom of the main or bottom level. At point 3 there are 4 sections, A R I for fun 3, A R I for fun 2, A R I for fun 1, and A R I for main. There are 2 cell stacks in fun 3 which read, parameter and dynamic link. There are 4 cell stacks in fun 2 which read, local, parameter, dynamic link, return to fun 1. There are 5 cell stacks in fun 1 which read, local, local, parameter, dynamic link and return to main. There is one cell stack in main which reads local. There are variables notated beside the stacks. In section fun 3 variable q is next to the parameter level. In section fun 2 variable y is next to local level and variable x is next to level parameter. In section fun 1 variable t is next to the first local level and variable s is next to the second local level. In section main, the variable p is next to the only level. Three lines run from the dynamic link level in section 3 to the bottom of section fun 2, the dynamic link level in section fun 2 to the top of the main or bottom level, and from the dynamic link level in fun 1 to the bottom of the main or bottom level.

At first call there are 2 sections, First A R I for factorial which means first activation record instance for factorial and A R I for main. There are 4 cell stacks for first A R I for factorial, functional value question mark, parameter 3, dynamic link with line to the bottom of A R I main, and return to main. There is one cell stack for A R I for main which is local question mark. The variable n is next to parameter 3 in the first A R I. The top line of first A R I is pointed to by an arrow labeled top. The word value is next to the main or bottom most level. At second call there are 3 sections, second A R I for factorial, First A R I for factorial which means first activation record instance for factorial and A R I for main. There are 4 cell stacks for second A R I for factorial, functional value question mark, parameter 2, dynamic link with a line to the bottom of first A R I section, and return to factorial. There are 4 cell stacks for first A R I for factorial, functional value question mark, parameter 3, dynamic link with line to the bottom of A R I main, and return to main. There is one cell stack for A R I for main which is, local question mark. The variable n is next to parameter 2 in the second A R I and parameter 3 in the first A R I. The top line of second A R I is pointed to by an arrow labeled top. The word value is next to the main or bottom most level. At third call there are 4 sections, third A R I for factorial, second A R I for factorial, First A R I for factorial which means first activation record instance for factorial and A R I for main. There are 4 cell stacks for third A R I for factorial, functional value question mark, parameter 1, dynamic link with a line to the bottom of the second A R I section, and return to factorial. There are 4 cell stacks for second A R I for factorial, functional value question mark, parameter 2, dynamic link with a line to the bottom of first A R I section, and return to factorial. There are 4 cell stacks for first A R I for factorial, functional value question mark, parameter 3, dynamic link with line to the bottom of A R I main, and return to main. There is one cell stack for A R I for main which is, local question mark. The variable n is next to parameter 1 in the third A R I, parameter 2 in the second A R I, and parameter 3 in the first A R I. The top line of third A R I is pointed to by an arrow labeled top. The word value is next to the main or bottom most level.

At position 2 in factorial third call completed there are 4 sections, third A R I for factorial, second A R I for factorial, First A R I for factorial which means first activation record instance for factorial and A R I for main. There are 4 cell stacks for third A R I for factorial, functional value 1, parameter 1, dynamic link with a line to the bottom of the second A R I section, and return to factorial. There are 4 cell stacks for second A R I for factorial, functional value question mark, parameter 2, dynamic link with a line to the bottom of first A R I section, and return to factorial. There are 4 cell stacks for first A R I for factorial, functional value question mark, parameter 3, dynamic link with line to the bottom of A R I main, and return to main. There is one cell stack for A R I for main which is, local question mark. The variable n is next to parameter 1 in the third A R I, parameter 2 in the second A R I, and parameter 3 in the first A R I. The top line of third A R I is pointed to by an arrow labeled top. The word value is next to the main or bottom most level. At position 2 in factorial second call completed call there are 3 sections, second A R I for factorial, First A R I for factorial which means first activation record instance for factorial and A R I for main. There are 4 cell stacks for second A R I for factorial, functional value 2, parameter 2, dynamic link with a line to the bottom of first A R I section, and return to factorial. There are 4 cell stacks for first A R I for factorial, functional value question mark, parameter 3, dynamic link with line to the bottom of A R I main, and return to main. There is one cell stack for A R I for main which is, local question mark. The variable n is next to parameter 2 in the second A R I and parameter 3 in the first A R I. The top line of second A R I is pointed to by an arrow labeled top. The word value is next to the main or bottom most level. At position 2 in factorial first call completed, there are 2 sections, First A R I for factorial and A R I for main. There are 4 cell stacks for first A R I for factorial, functional value 6, parameter 3, dynamic link with line to the bottom of A R I main, and return to main. There is one cell stack for A R I for main which is local question mark. The variable n is next to parameter 3 in the first A R I. The top line of first A R I is pointed to by an arrow labeled top. The word value is next to the main or bottom most level. In position 3 in main final results. There is one cell stack for A R I for main which is local question mark. The top line of first A R I is pointed to by an arrow labeled top. The word value is next to the main or bottom most level.

There are 5 sections labeled A R I for sub 1, A R I for sub 3, A R I for sub 2, A R I for big sub, A R I for main underscore 2. There is a label at the top reading top. Section sub 1 has 5 cell stacks, local, local, dynamic link which has a line that goes to the bottom of sub 3, static link which has a dotted line that goes to the bottom of big sub, and return to sub 3. The variable d is next to the top local and the variable a is next to the second local. Section sub 3 has 5 cell stacks, local, local, dynamic link which has a line that goes to the bottom of sub 2, static link which has a dotted line that goes to the bottom of big sub, and return to sub 2. The variable e is next to the top local and the variable c is next to the second local. Section sub 2 has 5 cell stacks, local, local, dynamic link which has a line that goes to the bottom of sub big sub, static link which has a dotted line that goes to the bottom of big sub, and return to sub big sub. The variable e is next to the top local, the variable b is next to the second local, and the variable x is next to parameter. Section big sub has 6 cell stacks, local, local, local, dynamic link which has a line that goes to the bottom of main, static link, and return to main. The variable c is next to the top local, the variable b is next to the second local, and the variable a is next to the third local. Section main has 1 cell stacks, local. The variable x is next to the local.

Three unlabeled levels proceed the block variables levels of e, d, c, b and g, and a and f. Locals levels read, z, y, and x. The bottom most level is a large shaded black that reads, activation record instance for main.

There are 5 sections labeled A R I for sub 3, A R I for sub 2, A R I for sub 1, A R I for sub 1, A R I for main. Section sub 3 has 4 cell stacks, local, local, dynamic link which has a line that goes to the bottom of sub 2, and return to sub 2. The variable z is next to the top local and the variable x is next to the second local. Section sub 2 has 4 cell stacks, local, local, dynamic link which has a line that goes to the bottom of sub 1, and return to sub 1. The variable w is next to the top local and the variable v is next to the second local. Section sub 1 has 4 cell stacks, local, local, dynamic link which has a line that goes to the bottom of sub 1, and return to main. The variable w is next to the top local and the variable v is next to the second local. Section main has 2 cell stacks, local and local. The variable u is next to the top local and the variable v is next to the second local.

There are 5 stacks that are labeled, u, v, x, z, and w. The names in the stack cells indicate the program units of the variable declaration. U has one cell stack labeled main. V has three cell stacks labeled, sub 1, sub 1, main. X has two cell stacks labeled, sub 3 and sub 2. Z has one cell stack labeled sub 3. W has three cell stacks labeled, sub 2, sub 1, sub 1.

The first block is the Public class A consists of a method draw and an incomplete line of code. The second block is the Public class B extends A consists of a draw method and an incomplete line of code. This block has an upward arrow pointing towards the first block. The client block consists of the following code. Line 1. A my A = new A (); Line 2. my A period draw (); Line 3. Incomplete line of code.

A stack with value variables b 1 and a 1 pointing towards its corresponding objects. variable b 1 points towards its objects X and Y. This is labeled data area. Variable a 1 points towards its object X. This is labeled data area.

The first illustration has three classes Shape, circle and rectangle with values virtual void draw left parenthesis right parenthesis = 0, void draw left parenthesis right parenthesis and void draw left parenthesis right parenthesis. The classes circle and shape are inherited from the class shape. Similarly class square can also be inherited. The second illustration displays the type of the pointers and it’s binding to objects. The shape asterisk pointer is represented as a rectangular block with reference p t r underscore shape binded towards its object square with value void draw left parenthesis right parenthesis. Similarly, The rectangle asterisk pointer is represented as a rectangular block with reference r e c t binded towards its object rectangle with value void draw left parenthesis right parenthesis. The binding is represented using a continuous arrow pointing towards the block. The square asterisk pointer is represented using a dot.

The class instance record for A is represented using a virtual method table with 3 fields, v table pointer, a and b pointing towards a v table for A with two fields. The two fields have pointers towards, code for A’s draw and code for A’s area. Similarly, the class instance record for B is represented using a virtual method table with 5 fields, v table pointer, a, b, c and d pointing towards a v table for B with three fields. The three fields have pointers towards, code for A’s area, code for B’s draw and code for B’sift.

The class instance record for C is represented using a virtual method table with 5 fields, v table pointer, a, v table pointer, b and c. The first v table pointer points to C’s v table for C and A part with 3 fields. The three fields have pointers towards, code for C’s in it, code for C’s fun and code for C’s d u d. The second v table pointer points to C’s v table for B part with one field that points towards code for B’s sum.

The value of total 3 is represented by a continuous line. Values 4 and 6 are written on the line. Task A is presented by a continuous line with markings Fetch TOTAL, Add 1 and Store TOTAL. Similarly, Task B is represented by a continuous line with markings Fetch TOTAL, Multiply by 2 and Store TOTAL. Time is represented by a continuous arrow pointing towards the right.

The flow of the states is as follows: A new state is created; The state then becomes ready with a task; The scheduled task begins running The task with time slice expiration returns back to the ready state; The completed task is sent to the dead state; The input or output from the running state is sent to the blocked state which, when completed goes back to the ready state.

The processes SUB 1 and SUB 3 are given to the insertion block for inserting data and the removed data is fed back to the processes. Insert sends information to buffer and remove received information from buffer.

The first timeline diagram depicts the occurrence, task example waits for sender. The timeline is represented using a continuous arrow pointing towards the right. The task example consists of the following steps in the time line: Wait at accept, Accept and wait at accept. Wait at accept is represented by dashed lines. The sender consists of the following steps, sends message, rendezvous and continue execution. The rendezvous section is represented in dashed lines. The second timeline diagram depicts the occurrence, sender waits for task example. The timeline is represented using a continuous arrow pointing towards the right. The task example consists of the following steps in the time line: Busy, Accept and wait at accept. Wait at accept is represented by dashed lines. The sender consists of the following steps, sends message and is suspended, rendezvous and continue execution. The rendezvous section is represented in dashed lines.

Task A has two jobs 1 and 2 and task B has two jobs 3 and 4, labeled, accept clauses. Both tasks consist of a task body connected to each other by a bidirectional arrow. A note beside reads, B period Job 3 value.

The flow transfers from the executing code to the exception handlers. The executing code consists of the following: Line 1, incomplete. Line 2, begin. Line 3, incomplete. Line 4, some statement. Line 5, incomplete. Line 6, end semicolon. Line 7, incomplete. The exception handlers consist of the following: Line 1, when incomplete line of code. Line 2. begin. Line 3.incomplete. Line 4, end semicolon. The exception is raised in, some statement. The control exception to handler binding, flows from some statement to the when statements. The when then continues back to the some statement in the executing code, the end, two incomplete sections, and a termination on the side.

The internal representation of the list A, B, C, D: A pointer points to the head node in the list. Four nodes with data parts A, B C and D and the next pointer linked to its successor. The node D does not have a successor and the pointer value is null. The internal representation of the list A left parenthesis B C right parenthesis D left parenthesis E left parenthesis F G right parenthesis right parenthesis: A pointer points to the head node A in the list. Node A is linked to Node B. Node B is linked to node D and Node C. The node C does not have a successor and the pointer value is null. Node D points to a dummy node for E with a null value. This node points to the node E which similarly points to a null node and points to Node F. This node F points to node G. The node G does not have a successor and the pointer value is null.

The internal representation of lisp list C O N S single quote A single quote left parenthesis right parenthesis which after construct operation becomes A. A head node with data part value A and null pointer value. The internal representation of lisp list C O N S single quote A single quote left parenthesis B C right parenthesis which after construct operation becomes A B C. Three nodes with data parts A, B and C and the next pointer linked to its successor. The node C does not have a successor and the pointer value is null. The internal representation of lisp list C O N S single quote left parenthesis right parenthesis single quote left parenthesis A Bright parenthesis which after construct operation becomes left parenthesis right parenthesis A B. A head node with data part value pointing towards another node with data part NIL. The head node points to a node with data part A and this node points to a node with data part B with a null pointer. The internal representation of lisp list C O N S single quote A B single quote left parenthesis C D right parenthesis which after construct operation becomes left parenthesis A B right parenthesis C D. The head node points to two nodes with data parts A and C. Node C points to a node with data part D and with a null pointer value. Node A points to a node with data part B and with a null pointer value.

Each goal is depicted by a rectangular box with four ports call, fail, exit and redo. The control enters the block through the call port or the redo port. If the goal succeeds, the control leaves through the exit port. If the goal fails, the control leaves through the fail port. If two sections are connected as in the example the redo and fail sections connect and the exit and call sections connect.

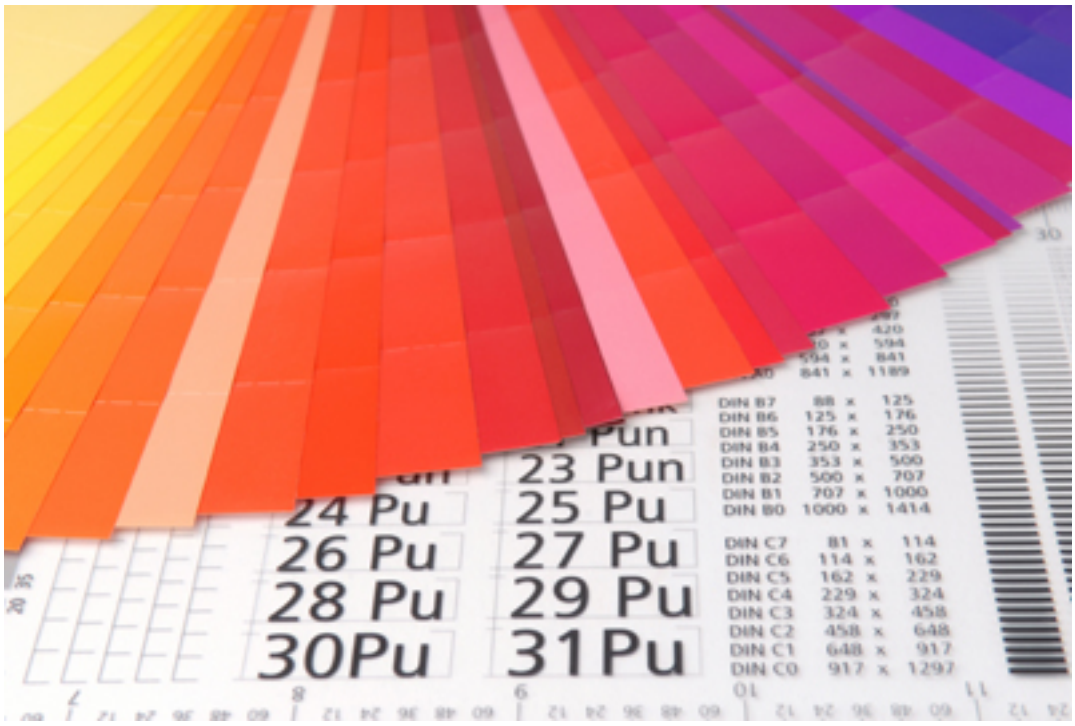
1. Why you need to be organised to be creative



"Be regular and orderly in your life so that you may be violent and original in your work."
Gustave Flaubert

So you start the day full of enthusiasm. You're excited about a new piece of creative work and itching to put your ideas into action. Firing up your computer, the familiar stream of e-mails pours into your inbox, burying the ones you didn't get round to replying to yesterday. Scanning through the list, your heart sinks – two of them look as though they require urgent action. You hit 'reply' and start typing a response to one of them… 20 minutes later you 'come round' and realise you've got sucked into the e-mail zone and have been sidetracked by interesting links sent by friends, as well as writing replies about issues that aren't a priority for you. You minimize the e-mail window and get back to your project…

After 15 minutes you're really enjoying yourself, getting into your creative flow – when the phone rings. Somebody wants something from you. Something to do with a meeting last week. You rummage through the papers on your desk, searching for your notes. You can't find them. Suddenly your heart leaps as you lift up a folder and find an important letter you'd forgotten about – it needed an urgent response, several days ago. 'Hang on, I'll get back to you' you tell the person on the phone, 'I'll ring you back when I've found it'. You put the phone down and pick up

the letter – this needs sorting immediately, but you remember why you put it off – it involves several phone calls and hunting through your files for documents you're not sure you even kept. By now, you've only got half an hour before your first meeting and you've promised to ring that person back. . Your design stares at you reproachfully. The e-mail inbox is pinging away as it fills up – already there are more messages than before you started answering them. Your enthusiasm has nosedived and the day has hardly begun. Creative work seems like a distant dream.

. . .

Is this a familiar scenario for you? Swap the design software for a wordprocessor and I've been there a hundred times. In an ideal world we'd be putting all our time and energy into creative work, but the realities of modern work often seem to be conspiring against us. And in lots of ways the scenario is getting worse. The wonderful thing about modern technology is the amount of communication and information-sharing it facilitates. And the awful thing about modern technology is the amount of communication and information-sharing it facilitates. We are deluged with new information and connections, via telephones, webcams, instant messengers, e-mail, websites, blogs, newsletters, wikis, and social networking technology. The list gets longer every year. And with Blackberry and the mobile internet you can have data and demands coming at you 24/7. No wonder people are starting to run workshops on 'digital stress'.

All of which is bad enough whatever your line of work. But if you're a professional artist or creative, it's even more damaging. Concentration is essential for creative work - certain stages of the creative process require single-minded focus on the task in hand. When we're really in the zone, we experience 'creative flow' – the 'almost automatic, effortless, yet highly focused state of consciousness' that psychologist Mihaly Csikszentmihalyi has identified as characteristic of high-level creative performance. Interruptions, multi-tasking and the anxiety that comes from trying to juggle multiple commitments – these are in danger of eroding the focused concentration that is vital for your creativity.

If you're worried about the effect of all those interruptions, frustrations and distractions on your creative work, this e-book is for you. Over the next seven chapters I will offer you some principles and practical methods for maintaining your creative focus under pressure, and for managing the stream of information and demands so that it informs and stimulates your creativity instead of drowning it out.

And that means being organised.

There, I've said it. Organisation, structure, discipline and habit – these often seen as threats to creativity. Not to mention corporate-sounding phrases such as 'time management' or 'workflow'. We like to think of creativity as a space for untrammelled imagination, free from all constraints. Yet while freedom, rule-breaking and inspiration are undoubtedly essential to the creative process, the popular image of creativity overlooks another aspect: examine the life of any great artist and you will find evidence of hard work, discipline and a hard-won knowledge of the rules and conventions of their medium. Choreographer Twyla Tharp, who directed the opera and dance scenes for the film *Amadeus*, has this to say about the film's portrait of Mozart:

> The film *Amadeus* dramatizes and romanticizes the divine origins of creative genius. Antonio Salieri, representing the talented hack, is cursed to live in the time of Mozart, the

> gifted and undisciplined genius who writes as though touched by the hand of God… Of course this is hogwash. There are no 'natural' geniuses… No-one worked harder than Mozart. By the time he was twenty-eight years old, his hands were deformed because of all the hours he had spent practicing, performing, and gripping a quill pen to compose… As Mozart himself wrote to a friend, "People err who think my art comes easily to me. I assure you, dear friend, nobody has devoted so much time and thought to composition as I. There is not a famous master whose music I have not industriously studied through many times."

This passage is taken from Tharp's excellent book *The Creative Habit: Learn it and Use it for Life*, in which she argues that 'routine is as much a part of the creative process as the lightning bolt of inspiration, maybe more'. It's an inspiring, challenging and very practical book that deserves a space on the shelf of anyone who takes their creative work seriously.

I'm not suggesting that all artists and creatives need to be 'organised' in a way that would satisfy a corporate boss. You might get up at noon and work at home in your dressing gown, in a pigsty of a living room. You might check into a different hotel room every day and work on the bed. Your creative process and working habits might look like total chaos to an outsider, but if they work for you, that's all that matters. And there will be some method in the madness – patterns in your daily activities that are vital to your creativity. These are the things you need to do to keep your imagination alive – whether it's sitting at a desk by 6am, using the same pen, notebook or make of computer, hitch-hiking across America, putting rotten apples in your desk so that the scent wafts into your nostrils as you work, or sitting in your favourite café with a glass of absinthe.

In this e-book, I will offer some suggestions for keeping the tide of external demands at bay and helping you to develop a truly creative routine and rhythm to your working day. I won't offer you a rigid system or any 'best practice' nonsense – just some principles and suggestions for you to try out and adapt as you see fit. As well as drawing on my own experience and study of the creative process, I'll refer to some well-known time- management systems and suggest what I think they have to offer creative professionals.

The next seven chapters will look at specific elements of personal organisation and time management, while the final chapter will be a list of further resources.

Questions

What is your attitude to organising your creative work? Do you see organisation as soulless, uncreative routine or as a necessary, helpful part of your creative process?

What effect does feeling muddled and disorganised have on your creativity?

Which areas of your work would you like to be more organised about?

What do you like about chaos? Where in your work do you want to give chaos and randomness free rein?

2. Prioritise 'important but not urgent' work

A couple of years ago, I was facing a brick wall. I was in the second year of a part-time Master's degree that was essential for my business. I was invited to edit an issue of Magma, one of the top poetry magazines in the UK – as a poet, this was a chance I couldn't turn down. I was also getting married, which took a fair amount of preparation too – and that was one opportunity I was definitely not turning down! Meanwhile, I somehow had to keep my business going, keep my clients happy and fund all these extra-curricular activities.

As if that weren't enough, I discovered this new phenomenon called blogging – or rather, discovered that people were using it to spread their ideas and promote their businesses, rather than just to write about their cat's breakfast menu. It looked like a perfect medium for me – I loved writing, I had ideas I wanted to get into circulation, and I loved connecting with new people. But where was I going to find the time?

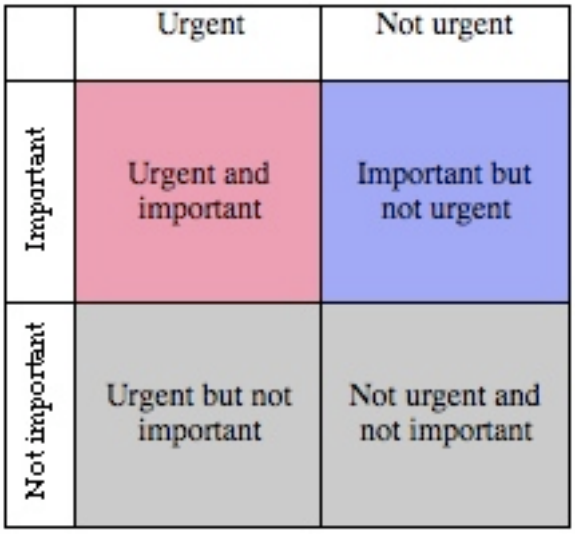
I'd already made a reluctant deal with myself to put my poetry-writing 'on-hold' until the end of the MA (on condition that I resumed afterwards, which I'm now doing with pleasure). But I was still faced with the seemingly impossible task of finding quality, focused time, away from interruptions, to write my essays, read poetry submissions with the care they deserved, and start a blog. After scanning my diary and surveying the tasks in hand, I was faced with a depressing conclusion.

I was going to have to get up early.

There was simply no other time in my schedule – or not the quiet, uninterrupted time I needed for my work, without the intrusion of phone calls, e-mails, meetings and classes. I had never considered myself one of nature’s early risers, and working from home much of the time had allowed me the luxury of avoiding early starts for commuting. On a good day I’d be up by 7.30, on a bad day it was closer to 8.30. Still time to get a reasonable amount of work done by starting at 9.00 – but I was faced with an unreasonable amount of work, so drastic action was called for.

My new start time became 6.30am. If you want to know how I managed this, read Steve Pavlina’s excellent post How to become an early riser. Here, I’m more concerned with the effect – since making the change, I’ve edited a postbag of 2,500 poems into Magma issue 34, achieved a distinction in my Master’s, and created the Wishful Thinking blog which has transformed my business and opened up many new creative avenues for me to explore. I’ve also written some poems I’m pleased with (at the moment, anyway) and which are gradually making it into publication. Most importantly of all, I made it to the wedding on time!

I’m not listing the above to blow my own trumpet, but to illustrate the value of ring-fencing time for your own creative work, in the midst of more urgent demands. It would have been easy for me to justify turning down the poetry magazine because I was too busy. It would have been even easier to put off starting the blog until I had more time. I could even have reasoned my way into stopping or deferring the Master’s. But the thing is, there will always be something ‘urgent’ taking my attention away from my own creative initiatives. Yet when I look back over the last couple of years, the time when I’ve created most value, for myself and my clients, has been those first hours of the day I’ve spent writing blog posts, essays, seminars and poems. It’s the creative wellspring that feeds into all the coaching, training, presenting and consulting I do when I’m face-to-face with clients.



Enough about me. How can **you** find time to achieve your creative ambitions?

Prioritise work that is ‘important but not urgent’

In his book The Seven Habits of Highly Effective People, Stephen Covey classifies work tasks according to whether they are important or urgent.

Covey points out that many of us spend too much time on tasks that are **urgent and important** (the red square in the diagram) – in other words, staving off emergencies by rushing around to solve problems or responding to others’ demands at short notice. Sometimes this is unavoidable – ‘deadline magic’ can spur us on to feats of creative production we wouldn’t otherwise attempt. This can be an exciting and productive experience – but it’s up to you whether you want to work like this most of the time. The example of the computer games industry – where extended ‘crunch’ times can mean endless overtime to meet a deadline – suggests that prolonged deadline magic can turn into deadline misery, with a significant impact on morale and efficiency.

Covey’s solution is to prioritise work that is **important but not urgent** (the blue square in the diagram). Though this is hard to do on any given day, it is the only way to ensure you are **making progress towards your own goals and dreams**, instead of merely reacting to what other people throw at you. And over time, the more you are dealing with important things before they become urgent, the fewer ‘urgent and important’ tasks you will have to deal with.

The most obvious way to do this is to work on your own projects first every day, even if it’s only for half an hour. Whatever interruptions come along later, you will at least have the satisfaction of having made some progress towards your own goals.

It’s obviously not just a question of time – you also need to **ring-fence your attention** so that you can devote your full attention to your creative work, without being knocked off course by distractions. The next chapter will look at how some highly creative people have achieved this, and what you can learn from them.

Questions

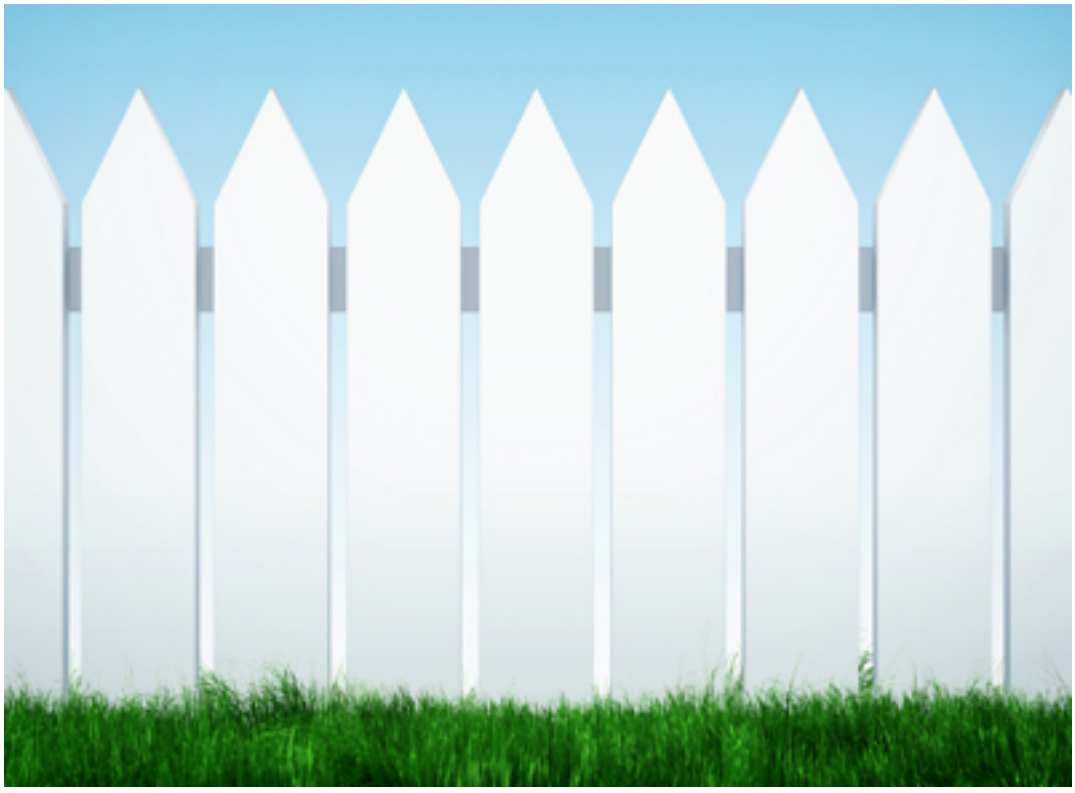
Think of the achievements you are most proud of, and that have added most value to your life and work. When you were working on them, how many of them fell into the ‘important but not urgent’ category?

How do you feel at the end of a day where you have made even a little progress towards a cherished goal?

How do you feel at the end of a day that has been totally swamped by others’ demands and urgent tasks?

What difference would it make to your life if you devoted more of your time to ‘important but not urgent’ work?

3. Ring-fence your most creative time



We've looked at the importance of prioritising 'urgent but not important' work. But how do you actually do this, and maintain the laser-like focus required for concentrated creative work, in the midst of all the demands and distractions of your working life?

Pick your most creative time of day

In my last chapter, I talked about my decision to get up early to write, before the onslaught of phone calls and other distractions. Apart from the lack of external interruptions, I write first thing in the morning because (once I'm up) that's the time of day when I'm most focused and alert. I experience a greater mental clarity in the first couple of hours of the working day than at any other time. As a writer, that quality of attention is my most valuable asset, so I've learned to guard it carefully. If I start ploughing into e-mails, reading blog feeds or doing mundane tasks such as accounts, then I'm squandering my most precious resource.

Victorian novelist Anthony Trollope puts me to shame with his habit of getting up at 5.30 to write his novels before breakfast. But early morning isn't the most creative time for everyone. We all have our own daily rhythms of alertness and rest. ProBlogger Darren Rowse says that 10am to 12pm are his "golden hours" for "thinking creatively and getting things done". Fellow blogger and

author of *The Four Hour Work Week* Tim Ferriss writes blog posts in two phases, at different times of day:

> Separate brainstorming (idea generation) from synthesis (putting it all into a flowing post). I generally note down 10-15 potential points for a post between 10-10:30am with a double espresso, select 4-5 I like and put them in a tentative order from 10:30-10:45am, then I'll let them marinate until 12am-4am, when I'll drink yerba mate tea, craft a few examples to match the points, then start composing. It's important to identify your ideal circadian schedule and pre-writing warm-up for consistent and reliable results.
> The Four Hour Work Week Blog

Writer Maya Angelou makes a similar distinction between time for writing the first draft and for revising it:

> I get up about five… I get in my car and drive off to a hotel room: I can't write in my house, I take a hotel room and ask them to take everything off the walls so there's me, the Bible, Roget's Thesaurus and some good, dry sherry and I'm at work by 6.30. I write on the bed lying down – one elbow is darker than the other, really black from leaning on it – and I write in longhand on yellow pads. Once into it, all disbelief is suspended, it's beautiful…
>
> After dinner I re-read what I've written… if April is the cruellest month, then eight o'clock at night is the cruellest hour because that's when I start to edit and all that pretty stuff I've written gets axed out.
>
> (From *Creators on Creating*, Ed. Frank Barron, Alfonso Montuori, Anthea Barron)

Ring-fence your attention – get yourself in the right state of mind

Maya Angelou's writing habits might seem eccentric, but they actually make complete sense. Writing in a hotel room effectively separates her writing time from the rest of her life, eliminating distractions and ensuring that she can enter a highly creative state of mind whenever she wants to.

My first professional training was in hypnotherapy, which taught me how sensitive the nervous system is to 'triggers' in our environment. The more intense the original emotion and the more unique the trigger, the stronger the emotional reaction will be. For example, if you think of a song you used to play with your first boyfriend/girlfriend, you will probably start to feel some of the emotions you felt with him/her without even hearing the recording. Supposing the song were Bowie's 'Moonage Daydream', you might get something of the same nostalgic/romantic feeling by listening to other glam rock songs, but not as strongly as whenever you hear the opening chords of 'Moonage Daydream' itself.

Looking at Angelou's account, she obviously experiences strong emotions whenever she is writing. And by confining her writing to a special place and time, she has trained her nervous system to associate her creative state with unique combination of different triggers – the early morning drive, the hotel room, blank walls, the Bible, *Roget's Thesaurus*, dry sherry, lying on the bed and yellow paper. No wonder she is in the 'zone' soon after entering the room!

Looked at from this perspective, many of the supposed eccentricities of creative people seem perfectly logical and reasonable. Here is Stephen Spender describing the working habits of himself and his fellow poets:

> Schiller liked to have a smell of rotten apples, concealed beneath his desk, under his nose when he was composing poetry. Walter de la Mare has told me that he must smoke when writing. Auden drinks endless cups of tea. Coffee is my own addiction, besides smoking a great deal, which I hardly ever do except when I am writing.
>
> (from *Creativity*, ed. P.E. Vernon)

Can you see how each of the poets is using a particular stimulus to trigger his creative state?

Maybe you have a special place you go to for focused creative work – a secluded office, a particular chair, a seat in your favourite café. Or you may have a favourite notebook, pen, software application or make of computer – using other tools doesn't feel quite right. Once you get into the habit of using these triggers, they form a kind of ritual, or process of self-hypnosis if you like, to help you reach that state of focused absorption Mihaly Csikszentmihalyi calls 'creative flow'.

I don't go as far as Maya Angelou, but I do have a morning ritual to help me get into the right frame of mind for writing. A cup of tea first, then filter coffee. Tea goes in the blue china 'Maneki Neko' mug. Coffee in a different cup, covered in Japanese calligraphy, from Kyoto (a city with wonderful associations for me). If I'm drafting poetry, the Mac is banished from the desk. I write on sheets of A4 with a black 0.5mm Muji pen. For other writing, I use the Mac and switch on Isolator to black out the whole screen except the window I am writing in.

Even if you have to work in the middle of an office, there are things you can do to minimise distractions and interruptions. Switch off your mobile phone. Put the landline on answerphone. Close your e-mail application. If the office noise is distracting, try listening to music on your headphones. Set up a signal (e.g. a 'Do Not Disturb' sign on your desk) to let your colleagues know they will interrupt you at their peril. Keep a notepad open and write down any tasks to do with other projects that occur to you while you are working. You can then consult the pad and get on with them after you have finished. (Writing them down will get them off your mind and leave you free to focus – more on this in Chapter 6.)

Finally, if you find yourself starting to procrastinate, here's an excellent tip from Mark Forster. Say to yourself: 'I'm not really going to start working on this piece, I'll just open up the file and look at it…'

Questions

When is your most creative time, when you are most alert and find it easy to focus?

If you could arrange your ideal schedule, what time would you ring-fence for focused creative work?

How close to your ideal schedule can you get within the constraints of your current situation?

Do you have a special place for creative work?

What physical triggers (such as pens, paper, computer hardware or software), rituals or routines do you use to get yourself in the right state of mind?

4. Avoid the 'Sisyphus effect' of endless to-do lists

Imprisoned in the ancient Greek underworld as punishment for his earthly crimes, Sisyphus was famously tortured by a never-ending task. He was condemned to roll a huge rock up a hill – only to watch it roll back down and have to start all over again.

Sound familiar?

Let's have another look at the scenario from the first chapter:

> So you start the day full of enthusiasm. You're excited about a new piece of creative work and itching to put your ideas into action. Firing up your computer, the familiar stream of e-mails pours into your inbox, burying the ones you didn't get round to replying to yesterday. Scanning through the list, your heart sinks – 2 of them look as though they require urgent action. You hit 'reply' and start typing a response to one of them… 20 minutes later you 'come round' and realise you've got sucked into the e-mail zone, and have been sidetracked by interesting links sent by friends, and getting involved in issues that aren't a priority for you. You minimize the e-mail window and get back to your project…
>
> After 15 minutes you're really enjoying yourself, getting into your creative flow – when the phone rings. Somebody wants something from you. Something to do with a meeting last week. You rummage through the papers on your desk, searching for your notes. You can't

find them. Suddenly your heart leaps as you lift up a folder and find an important letter you'd forgotten about – it needed an urgent response, several days ago. 'Hang on, I'll get back to you' you tell the person on the phone, 'I'll ring you back when I've found it'. You put the phone down and pick up the letter – this needs sorting immediately, but you remember why you put it off – it involves several phone calls and hunting through your files for documents you're not sure you even kept. By now, you've only got half an hour before your first meeting and you've promised to ring that person back. Your design stares at you reproachfully. The e-mail inbox is pinging away as it fills up – already there are more messages than before you started answering them. Your enthusiasm has nosedived and the day has hardly begun. Creative work seems like a distant dream.

There are two big problems with this way of working:

1. You are at the mercy of interruptions

Whenever you sit down to focus on your own work, you never know when your concentration will be broken – by an e-mail, a phone call, a request from a colleague, or even by yourself, when you suddenly remember something important that you've forgotten to do. Almost as bad is as the interruptions is anticipating them – you can never really relax and focus, because you know you could be derailed at any moment.

When I trained in hypnosis one of the things I learned was that if you want to create amnesia, you should keep interrupting people and/or change the subject. The hypnotic explanation is that memory is dependent on your state of mind, so when you change your focus, you're changing your state of mind – which makes it hard to remember what you were thinking about before. Think of a time when you were chatting to a friend in a restaurant or at a party and someone came over and interrupted you with a question – when they left, you both turned to each other and asked 'What were we talking about?'.

The bottom line is that **interruptions destroy your concentration**. And loss of concentration = loss of creative work. If you're not careful, you can end up in permanent 'reactive mode' – spending your time responding to others' demands and all the things you have to do instead of the one thing you really **wanted** to do today.

Let's face it, the interruptions aren't going away anytime soon. If they did, it would be a bad thing – it would mean you had no clients, colleagues, customers or collaborators. Obvious short-term fixes are to close your e-mail application, switch your phone onto answerphone mode and put a 'do not disturb' notice on your office door – as recommended in my previous chapter on how to **Ring-fence your most creative time**. But you can't do this all the time – and it doesn't solve your second big problem…

2. The 'Sisyphus effect' – a never-ending to-do list

The 'Sisyphus effect' is the result of endless to-do lists, which in turn are created by a constant stream of incoming demands. We start the day full of enthusiasm, but by the end of it, we've taken on so many new commitments that the to-do list is longer than when we started.

Productivity expert Mark Forster makes an excellent and (to me) surprising point about motivation:

> What is the best way to motivate yourself for your daily work? Obviously, enjoying your work and having a clear vision are very important, but I don't believe they are the most important things for keeping going during the daily grind. On the contrary, I believe that what gives us the most energy is the feeling of being totally on top of our work. If you are totally on top of something you have the energy to do it even if you don't particularly like the work.

I hadn't thought about it like that before, but on examining my own experience, I think he's right – when I'm faced with a limited number of things to do in a day, even if they aren't all particularly exciting, I generally feel motivated enough to get through them. But if I'm faced with a vaguely-defined, open-ended list of tasks, I can feel a sense of hopelessness and my energy drops. I can even find myself paralysed by inaction when faced with 3 or 4 really exciting pieces of work, if I don't think there's time to do them all.

You need to give yourself room to breathe!

Faced with the twin problems of unpredictable interruptions and the Sisyphus effect of never-ending tasks, you need to give yourself room to breathe, keep a clear head and stay focused on what you want to achieve. In short, **you need to install a buffer between others' demands and your response**. Otherwise you'll end up in permanently anxious and unproductive 'reaction mode'.

On the other hand, you need to find a way of fulfilling your commitments and giving others what they need from you within a reasonable timescale. Otherwise you'll quickly gain a reputation for unreliability and pay the penalty.

How can you manage this? I'll present one solution in the next chapter – a surprising and counter-intuitive idea that has transformed my own working life…

Questions

What effect do interruptions have on your creativity?

Do you recognise the Sisyphus effect? What does it do to your motivation levels?

What difference would it make to your working life if being derailed by others' demands was the exception rather than the rule?

What difference would this make to your creativity?

5. Get things done by putting them off till tomorrow

In the last chapter, I described the problems created by a never-ending stream of incoming demands: on the one hand, the constant interruptions can destroy the concentration required for creative work; on the other, endless to-do lists create the 'Sisyphus effect' – a feeling of hopelessness and demotivation.

In his excellent book *Do It Tomorrow*, Mark Forster provides a provocative and elegant solution to these problems, which transformed my working life. He suggests we create a buffer between incoming demands and our response – by making 'do it tomorrow' our default response to all requests. Not 'tomorrow' as in 'tomorrow never comes', but 'tomorrow' as in 'tomorrow'. Not today or the day after tomorrow, but tomorrow.

For example, here's Mark's solution to the never-ending stream of e-mail. In this system, on a typical day you only have to deal with one day's worth of e-mails – i.e. those that arrived yesterday:

1. Supposing you received 40 e-mails yesterday (once you've weeded out all the spam) – the first thing you do is move these 40 e-mails into a folder marked 'action'. These are the only e-mails you are going to deal with today.
2. Sit down and answer them all in one batch. Or at most, two or three concentrated bursts of effort.
3. Any e-mails that arrive in your inbox are collecting there for tomorrow – whatever you do, **don't** get caught up in responding to them, or you will find yourself back in Sisyphus' shoes, facing an endless task!

Of course there will be exceptions – sometimes you will receive an e-mail that has to be answered today – e.g. from your boss, demanding an urgent document by 5pm. But these should be the exceptions, rather than the general rule. Mark argues that most tasks are not nearly as urgent as we think they are – ask yourself 'Will there be a disaster if I don't answer this until tomorrow?' and the answer is usually 'no'.

'Doing it tomorrow' has several benefits:

- **Dealing with e-mails in one batch is more efficient**. You can get into 'e-mail mode' and zip through them in one go.
- **It's more motivating to deal with a finite number of e-mails than an ever-expanding inbox**. In other words, it cuts out the Sisyphus effect and presents you with a manageable task instead of a never-ending one.
- **Today's e-mails can't interrupt you** – because you're not going to respond to them today. I experience a feeling of relief each time I look at an e-mail containing a request and then 'let go' of it and return to the task in hand – confident that I will deal with it tomorrow.
- **You answer e-mails in a better state of mind** – so you're much less likely to take on unnecessary commitments by agreeing to something in order to get rid of the e-mail. You are also likely to make a more thoughtful and helpful response.
- **It doesn't really matter how often you check your e-mail**. Personally I can see the benefit of only checking e-mail once a day, but I'm not disciplined enough to resist, especially if I'm waiting for something important. This way, I can check my e-mail as often as I like without getting caught up in responding to it.
- **You deal with the difficult e-mails**. Most of us have a few 'tricky' e-mails that we put off answering for various reasons. But this system means you answer all the e-mails that came in yesterday – so you end up clearing out the difficult ones and getting them off your mind.
- **You know when you're finished for the day!** Once you've answered yesterday's e-mail, you're finished with e-mail today – how good will that feel?

The same principles apply to other communication channels: post, phone calls, text messages, commitments you take on at meetings. They all go into the in-tray for tomorrow. So at the start of every day, you know exactly how much you have to do to keep abreast of your commitments –

once you've dealt with a day's worth of e-mail, post, phone messages and verbal requests, you're free to get on with more interesting things. Like that design you've been itching to get back to.

N.B. This only applies to the reactive side of your work, i.e. requests coming in from others. Work initiated by you is a different matter – see the chapter on **Ring-fencing your most creative time**. Mark Forster suggests that you prioritise your own goals by devoting the first part of the day to a 'current initiative' of your own. But be wary of putting all your ideas for new initiatives into the in-tray for tomorrow, especially if you are the type of person who has a lot of ideas – I tried doing this when I first read Mark's book (not carefully enough) and put my back out by trying to do an absurd amount of work each day!

Yes but…

- **My in-tray already has hundreds of e-mails in it** – so did mine. Mark Forster suggests that you take all these e-mails and put them in a folder labelled 'Backlog'. Voila – an empty inbox! You can now implement the system by dealing with one day's worth of e-mail at a time. You should also set aside dedicated time to work through the backlog – because you have limited the size of the backlog, it can only get smaller, so every e-mail you deal with brings you closer to a cleared backlog.
- **People expect me to respond to them today**. Then manage their expectations. Sometimes it's a case of 'training' others to learn not to expect an instant response. On average, you're actually more likely to get back to them quicker using this system, since you're not overloading yourself by trying to answer everything as it comes in.
- **My boss expects me to respond today!** This is trickier. If you're lucky, your boss will listen to reason – you can explain your new system and s/he will be impressed by your efficiency and agree to wait until tomorrow unless it's really urgent. If not, then you can at least apply the system to everyone else you deal with.
- **I've got too much coming in!** Mark Forster is pretty blunt about this one – if you've got too many demands coming in on a regular basis then you need to scale down your commitments by saying 'no' and/or delegating more. It's not easy, but it's easier than carrying on with an impossible task.
- **I've got too many other things to do!** Beware of stuffing your diary so full of meetings and client appointments that you don't have time to do the rest of your work. And you don't need to keep up every single day. If I'm running a seminar all day I certainly won't be processing all my e-mails and post when I get home! They can definitely wait until tomorrow.

Mark covers all these objections (and more) in his book, *Do It Tomorrow* – he also offers many more invaluable suggestions, so if you're intrigued by the idea of 'doing it tomorrow', I highly recommend you get hold of a copy.

Do it tomorrow – or next week?

Mark Forster's 'do it tomorrow' system works for me, but it may not be right for you. Your work might follow different rhythms. 'Do it next week' might work better for you. Another productivity guru, Tim Ferriss says it's possible to manage by only checking e-mail once a week!!!

The key principle is to create a 'buffer' between the information and demands that are coming at you, and your response. That way you can get out of reactive mode, avoid the Sisyphus effect and spend more time on the kind of work that really inspires you.

Questions

What difference would it make to your work if you knew every morning how much work you had to get through that day?

Apart from 'do it tomorrow' how else could you create 'buffers' between incoming demands and your response?

6. Get Things Off Your Mind

So you're sitting at your desk, trying to focus on a piece of creative work – but it's hard to concentrate, there's something nagging at your attention. Suddenly it pops into your mind – you've forgotten something urgent! Or even worse, you get a phone call or an e-mail out of the blue demanding to know why you haven't delivered on a promise. Or you notice a post-it on the floor, which has fallen off your monitor, containing a reminder to DO SOMETHING VERY IMPORTANT… by yesterday.

If this happens to you often enough, you get used to living with a constant low-level anxiety – scanning your memory, your desk, your e-mails, you post-its, your scattered to-do lists – as you worry that you've forgotten something important. When you agree to do something, you may write it down – but can you be 100% sure you'll notice the note in time to do it? Or if you're out and about and make a commitment, how can you be sure you'll remember to put it on your to-do list when you get back to the office? Wherever you go, whatever you're doing, somewhere at the back of your mind you're wondering whether you've forgotten something vital that could blow up in your face at any moment.

How about this for an alternative?

> What if you could dedicate fully 100 percent of your attention to whatever was at hand, at your own choosing, with no distraction?

> It's a condition of working, doing, and being in which the mind is clear…
>
> Most people give either more or less attention to things than they deserve, simply because they don't operate with a "mind like water".

No, it's not an ancient Zen text – these words are lifted from David Allen's best-selling book on productivity, *Getting Things Done*. When I read this section of the book, I grasped the true value of having a system for managing your workload – not merely to be more productive but to **reclaim your own mind by clearing out unnecessary mental clutter** caused by trying to keep track of all your work commitments.

Before discovering the Getting Things Done system, I would typically have several to-do lists on the go at once, on different sheets of paper, not to mention the post-it notes stuck to my monitor. But I wasn't in the habit of writing **everything** down, so there were always several items I had to remember at any one time. I was vaguely aware that the effort to remember – and anxiety about forgetting – was taking up valuable mental energy and clouding my mind. I resented this all the more, because I had experienced the opposite. I had been on retreats where I had experienced a wonderful mental clarity and peace of mind after several days of silent meditation. But each time the retreat ended, I was frustrated when this clarity was eroded by the demands of everyday life.

When I read David Allen's book, I saw the possibility of experiencing the clarity of a 'mind like water' in the midst of my daily work. Apart from the obvious emotional benefits, I could see that it would help my creativity – the 'mind like water' state sounds very similar to creative flow as described by psychologist Mihaly Csikszentmihalyi: 'an almost automatic, effortless, yet highly focused state of consciousness'.

So how does David Allen suggest we can achieve this state of mind while dealing with the pressures of work?

Set up 'buckets' to capture your commitments

'Buckets' are physical or virtual containers where you capture important information, demands and commitments so that they can't 'leak' away and be forgotten. You should have as few of these as possible, but as many of them as you need.

Here are my buckets:

- **A plastic in-tray** for incoming letters, business cards, papers, meeting notes, scribbled to-do lists, etc.
- **My e-mail inbox**
- **The inbox on iGTD** – the software I use to manage my to-do lists
- **My two answerphones** (one mobile, one landline)
- **The 'Drafts' folder on my mobile phone** – I always carry my phone with me, so if I have an idea or make a commitment when I'm out and about, I write a text message to myself and save it in the drafts folder.

Important:

- **Put ALL your commitments into these buckets**. Even if I think I can remember a task easily, it will take up valuable mental space – if I put into one of these buckets, I will get it off my mind.
- **NEVER put a commitment anywhere but in your buckets**. If I don't put it in one of the above places, I have to assume it won't happen. So I've trained myself to do it. This was a bit odd at first, now it's almost automatic and I feel a slight sense of relief each time I get something off my mind and into a bucket.

Benefits

- **When you get things off your mind you can forget about them and give your full attention to whatever you're doing in the moment** – such as your creative work.
- **You'll stop forgetting important things** – the number of commitments I've forgotten has dropped dramatically since using this system.
- **You'll stop worrying about forgetting things** – see above.
- **You can easily review your commitments** – so you're less likely to take on more than you can manage.

So am I now living in a constant state of blissful peace and clarity? Not quite. If that's your goal then it's hard to beat the monastic routine. But I've definitely removed one big source of stress from my life – the effort of remembering important commitments and the danger of forgetting them. I've been using the 'buckets' system long enough to know that once I put a task in a bucket, I won't forget it. So once I've made a note, I can stop thinking about it and concentrate on whatever I'm doing right now.

Yes but…

- **I don't like the idea of having to write down all my commitments** – Neither did I. But once I tried the system, I found the benefits easily outweighed the effort. Now it's become a habit and I hardly notice it.
- **It's all very well capturing all this stuff in buckets, but how do I know I'll do anything about it?** That's what the next chapter is about…

Questions

What difference would it make to your life if you knew you would never forget another important commitment?

What would it be like if you could get your commitments off your mind and stay focused in the present?

What difference would it make to know that you could review all your current commitments by looking in 5 or 6 convenient ‘buckets’?

What buckets do you / could you use to capture your commitments?

7. Review your commitments

So you're ring-fencing your creativity, avoiding the Sisyphus effect of endless to-do lists and getting all your commitments off your mind and into buckets. So what happens next?

Obviously, there's no point capturing all those to-do items unless you're going to do something about them. Which means regularly 'emptying the buckets', reviewing your commitments and deciding what to do. How you do this and how often is up to you, but here are a few principles to bear in mind.

Why should you review?

1. First, and most obviously, to make sure you actually **do** the tasks on your to-do lists!
2. If you don't review the lists regularly, you'll soon stop trusting them and won't be able to use them to get things off your mind.
3. To think about how you're going to approach your work. It's tempting to 'get going' first thing in the morning, so you feel like you're getting things done – but whenever I do this, my day is always less productive and more stressful than on days where I take 10 minutes to review my commitments and decide how I'm going to tackle them.
4. It helps you step back and see the 'big picture' of your work, weigh up priorities and make decisions about your next steps.

5. Whenever you review your upcoming work and are confident you can get it all done, it will be a weight of your mind and your energy level will rise. If you review and find that you are **not** confident of getting it all done, then the review will be even more valuable – better to find out now than later on!

When should you review?

In his book *Getting Things Done*, David Allen suggests that you review your to-do lists as often as you need to in order to feel on top of things. I do a mini-review every morning when I look through my e-mails and other in-trays (from yesterday of course).

A larger-scale weekly review is one of the cornerstones of the Getting Things Done system. David Allen describes the weekly review as a time to:

- Gather and process all your 'stuff'
- Review your system
- Update your lists
- Get clean, clear, current and complete

I'll be honest and say I don't do the review every week. Some weeks simply feel too busy, other weeks I'm so caught up in what I'm doing that stopping to review seems like an unnecessary interruption. But whenever I do make time for it, I always feel better – the review gives me a clear sense of where I am and what I'm doing. I nearly always find something important that was in danger of slipping through the cracks. After finishing the review, I'm full of renewed enthusiasm for my work. So maybe I'll do it this week after all…

How should you review?

In his book, David Allen gives detailed instructions on performing a weekly review. But it's really up to you how you do it – the review is about doing whatever you need so that you feel on top of your work.

Here's what I usually do:

1. Empty all my 'buckets' (For a definition of buckets see the previous chapter, **Get things off your mind**.)
2. Review my diary.
3. Review my to-do lists, deleting anything I've done or am not going to do.
4. Decide on my priorities – which projects do I really want to move forward in the next week? How will I find time for them?
5. Backup my computer and blogs.

It's important to empty your buckets by **making sure you have a record of each task in a place where you will find it when you need to**. It's up to you how you manage your to-do lists – you might like to have one big list or several, on paper or in digital format. David Allen suggests you have different lists for different contexts – e.g. a list of phone calls to make by the phone, a separate list of things to do when you're in town etc. . .

I use iGTD to manage most of my lists – it's designed for the Getting Things Done system and allows me to assign tasks to both projects (e.g. 'Blog ideas') and contexts (e.g. phone calls or e-mails). When I empty my buckets, I transfer any tasks from meetings, answerphone messages, notes etc. to iGTD. There's no need to do this for e-mails, as the e-mails themselves serve as reminders of the tasks – I'm not finished until the inbox is empty.

Reading through that last paragraph, I realise how geeky I must sound! Well, I'll let my friends be the judge of that. The system probably sounds like a lot of work, but I hardly notice it any more. It took a while to get used to this way of working, but now it works so well for me, I take it for granted. Dealing with tasks in this way has almost become automatic, leaving my mind free to think about more interesting things.

On the subject of geekiness, it will probably come as no surprise to learn that Getting Things Done and similar systems can become an obsession with some enthusiasts. If you're not careful you can spend so long reviewing and tweaking your system that you never get round to actually doing the things on your list… Having said that, I've found the time I've invested in investigating these systems and changing my working habits has been repaid many times over. I hope this e-book helps you make your working life more productive, enjoyable and creative.

In my final chapter I'll point to some useful books, software and websites to help you fine-tune your own personal organisation system.

Questions

How often do you review your commitments? Daily? Weekly? Never?

What difference does it make when you make time to review?

What difference does it make when you're 'too busy' to review?

How do you review? Any tips you'd like to share?

8. Resources to help you get things done

In this e-book I've given you my take on time management and how it can help or hinder creative work. In doing so, I've taken elements from different systems, having assimilated them over time and adapted them to my own needs. If you are keen to investigate these systems, please make sure you try them one at a time! Otherwise you'll end up confused. It's worth devoting some time to working with a system until you know it really well, before deciding whether you need to add to it. The following are all resources I've used myself.

My 'GTD' delicious bookmark

My GTD del.icio.us bookmark is where I bookmark any web pages I find with useful material about time and workflow management. ('GTD' stands for 'Getting Things Done'.) If you subscribe to the RSS feed for this bookmark then you'll receive new recommendations as I find them.

Books about the creative process

The Creative Habit – Learn it and Use it for Life, by Twyla Tharp
Very down-to-earth, very practical, very inspiring. The famous choreographer shares her working

routine and argues passionately that inspiration doesn't come without a lot of perspiration, discipline and hard work. Highly recommended for anyone who takes their creativity seriously.

Creativity – Flow and the Psychology of Discovery and Invention, by Mihaly Csikszentmihalyi
Classic study of the creative process, based on the idea that peak creative performance is characterised by the state of creative flow, in which distractions are tuned out and there is a single-minded focus on the work. Achieving more creative flow is one of the main reasons for a creative person to learn about time management.

Creators on Creating, edited by Frank Barron, Alfonso Montuori, Anthea Barron
A rich collection of first-hand accounts of the creative process, including some fascinating descriptions of creators' working habits. Contributors include Leonardo da Vinci, Brian Eno, Ingmar Bergman, Isadora Duncan, Richard Feynman, Rainer Maria Rilke and Frank Zappa.

'Do it tomorrow' – Mark Forster's approach

Do It Tomorrow and Other Secrets of Time Management, book by Mark Forster
If you're pushed for time and want a book on time management that will deliver results fast, this is the one I recommend. The book is deliberately provocative, prompting you to reconsider working habits you take for granted and full of non-obvious suggestions that make complete sense once Mark has explained his reasoning. Not only that, the ideas work and can be applied almost immediately.

Mark's system is not as complex as David Allen's (see below) but that doesn't mean it's less powerful, it's just different. It may well be all you need.

Mark also writes a lively and useful blog, Get Everything Done and provides a selection of Time Management Articles.

'Getting Things Done' – David Allen's system

Getting Things Done - How to Achieve Stress-Free Productivity, book by David Allen
David Allen's 'Getting Things Done' is a powerful system with legions of devoted fans. It's not for the faint-hearted however - once you've read the book it takes 2-3 full days of work to capture all of your commitments and set up the system. Having done this, I would definitely say it's been worth the time and effort, even if it means sacrificing a weekend.

David Allen's website - lots of resources, including free articles, a blog and forums.

Productive Talk Podcast - Merlin Mann Interviews David Allen about his system.

Getting Things Done Guru David Allen and His Cult of Hyperefficiency - Wired Magazine feature on the origins of Getting Things Done.

Getting Design Done - excellent piece about the Getting Things Done system and Creativity, from D. Keith Robinson at Graphic Define.

Implementing GTD for Creative Work? Merlin Mann of 43 Folders responds to Keith Robinson's article and asks whether GTD and creativity are compatible - prompting an interesting discussion in the comments.

Software

If you're a Mac user, Isolator will help you concentrate on your work by blacking out everything on your screen except the menu bar and the application you are currently working in. I gather Dropcloth does the same for Windows.

I use iGTD to organise my projects and 'to do' lists. It's flexible and reasonably user-friendly.

When I had a PC I used Thinking Rock which has similar functionality.

Blogs

43 Folders is a hugely popular GTD blog, run by Merlin Mann. A vast archive of tips and techniques for improving your productivity. I'm tempted to say I don't know how he finds the time, but I'll resist.

Lifehacker is a constant stream of potentially useful productivity tips, many of them tech-oriented, e.g. Manage a to-do list with your iPod touch. There are lots of posts published every day, but it doesn't take long to read - I just skim through the headlines until I find something useful.

Lifehack.org is another deservedly busy and popular productivity blog, run by Leon Ho and his team.

The Four Hour Work Week - As the title of his book *The Four Hour Work Week* suggests, Tim Ferriss offers a radical and provocative approach to rethinking your work and life. It goes far beyond time management and is a stimulating read for anyone who feels overloaded with work and wants to spend their time doing more interesting things. I first heard about Tim's ideas through this interview with Darren Rowse of Problogger.

Stationery

The Behance team specialise in helping creative professionals 'make ideas happen'. They espouse a philosophy of 'productive creativity', embodied in their Action Method and in their range of products for capturing and processing creative ideas. I blogged about their Action Pad for creative meetings a while ago.

There's an argument that having good quality tools will encourage you to use them more. Since buying some Moleskine notebooks earlier this year I've definitely noticed my fingers itching to scribble down more creative ideas and lines of verse.

9. If you found this e-book helpful...

Share it with a friend or colleague

If you know someone else who might find this e-book helpful, feel free to send it to them. Under the terms of the Creative Commons licence, you are free to copy and share this document, as long as you do not sell it, and as long as you keep it intact and credit me as the author.

Subscribe to the Wishful Thinking blog

I write the Wishful Thinking blog to share tips and inspiration for creative professionals, based on my experience of coaching artists and creatives since 1996.

You can have the latest blog posts delivered to you (free, of course) via RSS or E-mail. (If you're new to RSS, have a look at my What is RSS? page.)

Join the discussion on the original blog series

The chapters of this e-book were originally published on Business of Design Online, which offers a wealth of resources from specialist authors, about the business side of working in the design industry. Click on the headings read the posts on BoDo and join the discussion in the comments.

1. Why you need to be organised to be creative
2. Prioritise work that is 'important but not urgent'
3. Ring-fence your most creative time
4. Avoid the 'Sisyphus effect' of endless to-do lists
5. Get things done by putting them off till tomorrow
6. Get things off your mind
7. Review your commitments
8. Resources to help you get things done

Subscribe to Business of Design Online

Subscribe to Business of Design Online to receive more information, tips and advice on the business of graphic design, via RSS or E-mail.

10. The author and publisher

Mark McGuinness - Author

Mark is a poet and a business coach who runs Wishful Thinking - a specialist consultancy for creative professionals and agencies, studios and other companies in the creative industries sector. He writes the Wishful Thinking blog to provide practical tips and inspiration for creative professionals of all descriptions.

Mark originally qualified as a psychotherapist and has an MA in Creative & Media Enterprises from the University of Warwick, UK. His poetry blog is Mark McGuinness|poetry. E-mail Mark.

Business of Design Online - Original Publisher

The text in this e-book was originally published as a series on Business of Design Online, which provides a wealth of information, tools and techniques for successfully managing and marketing a design practice.

BoDo was conceived and created by three seasoned professionals, hailing from three continents – Catherine Morley, based in Bangkok, Thailand, Jeanette (Jay) Wickham, based in Melbourne, Australia and Neil Tortorella, based in North Canton, Ohio, USA. Along with their various additional skills, each is a communication designer who've run their own businesses for many years.

On BoDo you'll find continuously updated resources for running a design shop, including select e-books, business forms, excellent articles and more. The team contributes regular blog posts along with guest authors who will share their business experiences.

Morley and Tortorella were also instrumental in the development of Creative Latitude (CL), a popular resource site for designers, writers and other creatives. BoDo and CL will be sister sites, complimenting each other in terms of audience and content. While BoDo is targeted to those who are just setting up their business, CL is targeted toward those with a a few years experience.

Programme name	Industrial Engineering / Engineering Management
Independent higher education institution where the programme is being executed	University of Novi Sad
Higher education institution where the programme is being executed	Faculty of Technical Sciences
Educational-scientific/educational-art field	Technical-Technological Science
Scientific, proffesional or art field	Industrial Engineering and Management
Type of studies	Doctoral Academic Studies
Study scope, expressed in ECTS	180
Academic degree, abbreviation	Doctor of Science - Industrial Engineering and Engineering Management, Ph.D.Ind.Eng.Managem.
Study length	3
Programme implementation starting year	2005
Future course implementation starting year (for new programme)	
Number of students attending this programme	37
Planned number of students to be enrolled in this programme	120
Programme approval date (state the approval issuer)	14.11.2012 - Science Education Council 29.11.2012 - University of Novi Sad Senate
Programme language	Serbian, English
Programme accreditation year	2008
Web address containing programme information	http://www.ftn.uns.ac.rs

Standard 00. Higher Education Institution Competence for the Implementation of PhD Studies

The Faculty is fully prepared in terms of academic staff, classroom capacity and other facilities for administering doctoral studies in all the fields studied at the Faculty based on indicators related to scientific and research work. The Faculty has a short-term and long-term plan and is accredited as a scientific and research institution, as required by law.

The ability of the Faculty to administer doctoral studies can be indicated by the following criteria:

•the number of Ph.D. and Master theses defended at the higher education institution which are in the area for which the study programme is accredited, in terms of the ratio of the doctoral and master theses and the number of students who have graduated from the programme and the number of professors.

•the ratio between the number of professors and the number of professors involved in scientific and research projects.

•the ratio between publications in the Ministry of Science acclaimed international journals in the last 10 years and the number of professors.

•cooperation with institutions in the country and abroad.

The capability of the Faculty to administer doctoral studies is obvious from the references which are enclosed with the accreditation material.

Standard 01. Programme Structure

The name of the Doctoral Study Programme is Industrial Engineering and Engineering Management. The acquired academic degree is a Doctor of Philosophy in Industrial Engineering and Management. The outcome of the learning process is the knowledge that enables students to become capable of independent scientific research.
Doctoral studies in Industrial Engineering and Engineering Management last three years and they are worth at least 180 ECTS. It is 90 ECTS obtained through examination of the subjects, 30 ECTS laying theoretical basis for doctoral dissertations, and 60 ECTS are acquired by the drafting and defense of the doctoral dissertation.
Doctoral studies last at least three years (six semesters) and no longer than ten academic years.
Research study on theoretical grounds is a doctoral dissertation qualifying exam for the preparation of a doctoral thesis in which students demonstrate that they mastered necessary theoretical knowledge in the scientific areas of interest. Theoretical foundations are laid as examination (written and / or oral) in certain fields of study (issues) from at least three courses defined in the study programme.
Studies on doctoral studies are organized through lectures, research work, scientific research, development and defense of the doctoral dissertation.
Student`s research interest is profiled by selecting the course which will be studied and taken; and thus, contribute in-depth knowledge and understanding of areas (themes) of his doctoral dissertation. Optional courses are selected from the group of proposed subjects of study programme, but the students have the opportunity to choose a number of courses, with the consent of the mentor, from a set of subjects for Doctoral Studies at Faculty of Technical Sciences, University of Novi Sad, or any other university in the country or abroad. At the same time the conditions prescribed for lecture attendance in selected cases have to be fulfilled.
Teaching activity for the courses (compulsory or optional) is a group or individual (mentoring) activity. Group classes are held when the course was chosen by five or more students or when this type of training is necessary to organize due to the nature (character) of the subject-matter. The decision on the type of instruction and optional courses that are taught is taken by the Head of Doctoral Studies with the consent of the Manager of Doctoral Studies at the Faculty.

Standard 02. Programme Objectives

The purpose of this Study Programme is education of students capable of high quality and independent scientific research in accordance with the needs of our society. On the other hand, educating staff who are trained to critically evaluate research work and independently carry out original and scientifically relevant research enables the development of new technologies and procedures that contribute to the overall development of society. In addition, the purpose of this Doctoral Study Programme is a contribution to our national science as well as the application of new scientific solutions in the industry and in broader areas of energy, telecommunications, electronics and computing.
Study Programme at Doctoral Studies in Industrial Engineering/Engineering Management is designed to provide acquisition of skills that are socially justified and useful. The Faculty of Technical Sciences defined tasks and goals for educating highly competent personnel in the field of technology. The purpose of this Study Programme is completely in line with high objectives and goals of the Faculty of Technical Sciences and at the level of strict standards of education in the Ph.D. in Industrial Engineering/Engineering Management.

Standard 03. Programme Goals

The objective of the study program is to achieve student`s scientific competencies and academic skills in the field of Industrial Engineering/ Engineering Management. Besides, this includes the development of creative abilities of considering the problems and the ability of critical thinking, development of teamwork skills and mastering specific practical skills necessary to perform the profession.
The objective of the study program is to educate an expert who has sufficient extended knowledge consistent with contemporary directions of development of science in the world.
One of the specific objectives which is in accordance with educational aims of experts at the Faculty of Technical Sciences is to develop students` awareness of the need for a personal contribution to the development of society in general and environmental protection. The objective of the study program is also the education of experts in the field of teamwork, and development of technical capacity for communication and presentation of their original results to scientific public.

Standard 04. Graduates' Competencies

PhD graduates of the academic study programme in Industrial Engineering/Engineering Management are competent to conduct research and solve problems in real life practice activities. Competencies include, above all, the development of critical thinking skills, the problem analysis capabilities, the synthesis solution, predicting the behaviour of selected solutions with a clear representation of what the advantages and disadvantages of the selected solution.
Qualifications that indicate the completion of doctoral academic studies are gained by students:
•who have demonstrated systematic knowledge and understanding in the field of Industrial Engineering/Engineering Management which is the basis for developing critical thinking and application of knowledge;
•who have mastered the skills and methods of research in the field of Industrial Engineering/Engineering Management;
•who have shown the ability of making concepts, design, construction and application of the selected solution;
•who have shown the ability to adapt the research process with the necessary level of academic integrity;
•who have performed original research work, extending the existing boundaries of knowledge, which is verified by publishing papers in the appropriate scientific journal and by the references at national and international levels;
•who are capable of critical analysis, evaluation and synthesis of new and complex ideas;
•who are capable of knowledge and ideas transfer to their colleagues, wider academic community and society in general
•who are capable of promoting technological, social and cultural progress in the academic and professional environment
After graduation, PhD programme allows students to have the knowledge, skills, developed abilities and competencies to :
•independently solve practical and theoretical problems and organize and realize developing activities and research;
•be involved in international scientific projects
•be able to implement the development of new technologies and procedures in the field of electrical and computer engineering and to understand and use modern knowledge;
•think critically, work creatively and independently;
•respect the code of ethics and principles of good scientific practice;
•be capable to present scientific research results at scientific conferences and publish in scientific journals, verifying them through patents and new technical solutions;
•contribute to the development of scientific disciplines in science generally.
After this study programme completion, the student obtains the following subject-specific competences:
•thorough knowledge and understanding of the disciplines that are the subject of their involvement;
•ability to solve problems using scientific methods and procedures;
•linking basic knowledge in various fields and their application;
•ability of follow modern developments in the field of profession;
•necessary skills and ability in applying knowledge in the field of industrial engineering/engineering management;
•the use of information and communication technologies
Students are trained to design, organize and manage production. During training the student acquires the ability to independently perform experiments, statistical analysis of results and to formulate and adopt the appropriate conclusions.
Students who complete their doctoral studies in Industrial Engineering / Engineering Management gain knowledge on how to economically use the natural resources of the Republic of Serbia in accordance with the principles of sustainable development.
Particular attention has been focused on developing the capacity for teamwork and the development of professional ethics.

Standard 05. Curriculum

The curriculum of the Doctoral Academic Study Programme Industrial Engineering/Engineering Management is made to meet the set goals. The structure of the study programme enables the students to choose optional courses which will be worth at least 70%.
During the course of the doctoral academic studies students are encouraged to specialize in the specific field of study they are most interested in. Through optional courses they are able to take further interest in the scientific and research areas studied during the course of their graduate academic studies.
All courses last one semester and are worth a certain number of ECTS credits.
The curriculum defines every course of the study programme which states the following: the course name, type, the year and semester when the course is lectured, the number of ECTS credits, the name of the lecturer, the course objective with the expected outcome, the knowledge and competences the student will acquire, the prerequisites for taking the course, the course content, the recommended literature, the methods of lecturing, the knowledge tests and evaluation and other relevant data. Each course is designed in such a way to provide about half of the class load in the form of lectures and half of class load in the form of research. The research is an independent work of the PhD student, who has been doing the detailed study in the field of the selected course, as agreed with the course teacher.
The study programme is consistent with European standards regarding enrolment requirements, duration of study, terms of enrolling into the next year of studies, the acquisition of a diploma and mode of study.
The curriculum enables students to attend 7 courses during the first three semesters. In the first semester three compulsory courses are taught, namely: The research method and Selected topics in industrial engineering/engineering management and one optional course. In the second and third semester (each contains two optional courses), students elect optional courses after consulting their mentor, being available to every student of doctoral studies.
Lectures in teaching subjects are performed as a group or individual (mentor) classes. Group classes are held when there are five or more students studying particular subject, or when this kind of teaching is necessary to organize because of the nature (character) of the teaching subject.
The Manager of doctoral studies with the consent of the Chief of doctoral studies at the Faculty takes the decision on the type of instruction and elective courses.

Table 5.2 Course specification

Course:	Scientific Research Method
Course id: DZ001	
Number of ECTS: 5	
Teachers:	Atanacković M. Teodor, Folić J. Radomir
Course status:	Mandatory

Number of active teaching classes (weekly)

Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:

Precondition courses: None

1. Educational goal:

To enable students for successful writing of scientific papers and doctoral dissertations.

2. Educational outcomes (acquired knowledge):

- Ability of understanding varius scientific metods witch was used in scientific literature
- Ability of successful managing in proffesonal literature
- Ability of successful writing of scientific paper in area of of interests
- Ability of successful creating and ending of doctoral dissertation

3. Course content/structure:

Definition of science. Development of science through history.
Scientific methodology.
General and special scientific methods.
Structure of a scientific paper. Types of scientific results.
Writing and publishing scientific papers.
Writing the doctoral dissertation.
Evaluating scientific results.

4. Teaching methods:

Lectures. Consultations with students. Seminar paper.

1. Educational goal:

The educational goal is to introduce students to doctoral studies in Industrial Engineering and Management, to learn about the history and development of the field and learn the general settings that apply in this area.

2. Educational outcomes (acquired knowledge):

The student is competent to apply global settings of this area in further education in vocational subjects.

3. Course content/structure:

A review of research in the fields of organization and business management, innovation and entrepreneurship, project management, investment management, information management, quality management and logistics, risk management and insurance management, industrial engineering, marketing and media, human resource management, energy management, planning, organization and systems management, automation, and information-management systems and kominikacionih quality and logistics.

4. Teaching methods:

Mentor together with the student selects one or more modules depending on the scope of the module. Consultation. Lectures are delivered in combination. Theoretical part is followed by the examples that clarify the theoretical part of the curriculum. In addition to lectures, consultations are held regularly. Student independently deepens the subject-matter learnt at lectures through his research work while studying scientific journals and other literature. In addition to working with the teacher, students are trained to write their own scientific papers.

Precondition courses: None

1. Educational goal:

To acquire knowledge which can be used in professional subjects and practical work, develop and solve mathematical models for engineering courses using the knowledge gained through selected chapters in mathematics.

2. Educational outcomes (acquired knowledge):

Student will have been competent enough to develop and solve mathematical models in further professional education.

3. Course content/structure:

Student can choose in consultation with programme supervisor, one of the suggested modules: 1. Numerical Mathematics, 2. Optimization. 3. Pattern Recognition. 4. Partial Differential Equations, 5. Nonlinear Equations. 6. Computational geometry. 7. Elements of Functional Analysis. 8. Combinatorics. 9. Graph Theory.10.Operational Research- Linear Programming. 11. Probability 12. Statistics .13.Stochastic Processes. 14. Vector analysis. 15. Complex Analysis. 16. Linear Algebra. 17. Differential and Difference Equations. 18. Euclidean and Non-Euclidean Geometry. 19. Fractional Calculus,Differential Equations . 20. Operational Research-Quiuing theory. 21. Logic in Computing. 22. Discrete Mathematics. 23. Higher order Logic. 24. Theory of Mobile Processes. 25. Numerical Methods of Linear Algebra. 26. Fuzzy Sets. 27. Economic and Financial Mathematics. 28. Groups and Algebras Li. 29. Formal Languages and Automata Theory. 30. Process Algebras. 31. History of Mathematics. Part of the course is in the form of independent research and study in the field of mathematics. Study and research work is based on primary scientific sources, organization and conduction of experiments and statistical data analysis, numerical simulations, and possible paper in the field of mathematics.

4. Teaching methods:

Lectures. (The student can choose in consultation with supervisor, one or more modules depending on module scope). Consultations. Lectures are organized in combined form. The presentation of the theoretical part is followed by the corresponding examples which contribute to better understanding of the theoretical part. In addition to lectures there are regular consultations. Through research and study work the student will, on the bases of scientific journals and other relevant literature that has been studied independently, develop further understanding of the material covered in lectures. Working with the course teacher the student develops the ability to independently work on a scientific paper.

Course:		Selected Chapters in Non-Industrial Robotics			
Course id:	HDOK-2				
Number of ECTS:	14				
Teacher:		Borovac A. Branislav			
Course status:		Elective			
Number of active teaching classes (weekly)					
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:	
5	0	0	4	0	
Precondition courses		None			

1. Educational goal:

The course goal is to make students, having in mind their previous knowledge and interests, familiar with the new topics in the field of Non-Industrial Robotics, which is a field that is becoming increasingly more important, and to introduce them to research study.

2. Educational outcomes (acquired knowledge):

The expected educational outcomes of this course are the student`s knowledge and ability to fully understand the topics and issues related to Non-Industrial Robotics and his/her involvement in research work in this field of study.

3. Course content/structure:

In accordance with the student`s interests, some of the following topics will be further studied: applications for service robots (in a household, on a building site, in a hazardous environment, inspection robots, life saving robots, etc.), autonomous robots, control and regulation in biological systems, the comparison of the `control architecture` of biological systems and autonomous robots, types of autonomous robots depending on the way in which they move (wheels and tracks, jumping robots, snake-like robots, flying robots, multiple-legged and two-legged robot locomotion, etc.), robot learning, “behaviour-based robotics” which represents a new way in which we control robots in an unstructured environment like ours, grasping and manipulation of objects, humanoid robots. A part of the course work is conducted through independent individual study and research work in the field of Non-Industrial Robotics.The research study requires the student`s active and constant interest in and reading of the primary scientific resources, the organization and conducting of experiments and statistical processing of data, numerical simulations, writing a paper in the specific scientific field relevant to the doctoral dissertation

4. Teaching methods:

Depending on the number of students the course can be carried out either through lectures, or by working with a mentor (tutorial work). Modes of teaching depend on the number of students and the chosen chapters (topics). Students are involved in the research study work.

1. Educational goal:

The objective of the course is to obtain actual knowledge in the field of working process automation which is used in production and service systems and to introduce research problems.

2. Educational outcomes (acquired knowledge):

The outcome of the course is to obtain knowledge that enables students to systematically carry out working process automation in modern production and service systems as well as the knowledge and students` ability for independent and group research and research in this area.

3. Course content/structure:

Pneumatic, hydraulic and electrical systems automation. Energy efficiency of pneumatic systems. The quality of compressed air. Correlation requirements for air pressure and implementation methods. Effective filtration of compressed air. Automation filtering. Vacuum technology in automation.

4. Teaching methods:

Teaching activity is conducted through lectures and consultations. Preparation and defense of the scheduled project and passing the final examination. Prerequisite for taking the final examination is to complete and defend the project successfully. The final examination is written and refers to theoretical issues.

Precondition courses: None

1. Educational goal:

The objective of the course is students` understanding of the state-of-the-art approach in the development of fundamental managerial field of study and study research.

2. Educational outcomes (acquired knowledge):

The outcome of the course is students` obtained knowledge for independent and group research and research work in basic areas of management.

3. Course content/structure:

- DZ-08 Access to working process management
- Just-In-Time, Lean Producton
- Virtual enterprise
- Agile manufacturing
- Management of business processes
- Intelligent enterprising

4. Teaching methods:

Lectures: (Mentor and student select one or more modules depending on their volume). Consultation. Lectures are conducted in combination. Presentation of the theoretical part is followed by the examples that clarify the theoretical part of the curriculum. In addition to lectures, consultations are held regularly. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures. In addition to working with the teacher, students are trained to write their own scientific and research articles.

1. Educational goal:

The goal of the course is to enable students to understand the latest approaches in the development of production and service technologies, the structure of production and service systems, their organization and management in accordance with their prior knowledge and interests, as well as to introduce research work in this particular field of study.

2. Educational outcomes (acquired knowledge):

The outcome of the subject is the knowledge and student`s ability to understand the issues of effective production and service systems and engage in research work in this field.

3. Course content/structure:

- Changes in the manufacturing and service systems.
- Contributions in development of production and service systems: CIM, Lean production, effective production systems.
- The principles in the development of production and service systems.
- Characteristics of production and service systems.
- Development of effective structures of production and service systems.
- Grouping on the basis of the classification system.
- Grouping based on similarity of procedures.
- The spatial structure and location system.
- Automation of processes of designing the structure of effective production and service systems.
- Simulation of production and service systems.
- Organization technology of effective production and service systems.

4. Teaching methods:

Lectures: (Mentor and student select one or more modules depending on their volume). Consultation. Lectures are conducted in combination. Presentation of theoretical part is followed by the examples that clarify the theoretical part of the curriculum. In addition to lectures, consultations are held regularly. Precondition courses: None

1. Educational goal:

Development of the awareness of the need for a multidisciplinary point of view and multimethodological approach to the research of modern information and communication systems. Overview and analysis of the different architectures of modern information systems, point out possible directions for their development. To enable students to participate in the development of new models and concepts of the development of information and communication systems.

2. Educational outcomes (acquired knowledge):

Students gain knowledge about the architecture of modern information systems; learn new and alternative approaches to research and design of information and communication systems.

3. Course content/structure:

The architecture of information systems. Distributed systems, hardware and software concepts. Client-server model. Service-oriented business models and information technology. Review of current networking technologies. The communication software and protocols. Internet services: traditional, contemporary and developmental trends. Web technologies to support new business models. Interoperability of information systems. The integration of data from different sources. Incomplete information systems with structured data. Mobile information systems and services.

4. Teaching methods:

Teaching activity depends on the number of students, i.e. mentor or frontal approach. During the course students are required to develop and defend a research paper.

Precondition courses: None

1. Educational goal:

Teaching activity enables students to master the concept of bihevioral approach in finance, with strategic choices of measures and analysis of operational implications. The most important educational objectives are: 1) definition of action and the importance of psychological factors in decision making in finance, 2) introduction to the key psychological factors that occur in different areas of corporate finance, 3) understanding the errors that occur in making decisions due to psychological factors.

2. Educational outcomes (acquired knowledge):

Students will gain knowledge in the field of behavioral corporate finance and learn about the latest trends in finance.

3. Course content/structure:

1) The definition of behavioral finance
2) Determining the value of projects
3) Capital budgeting
4) Risk
5) Inefficient markets and corporate decisions
6) Capital Structure
7) Dividend Policy
8) Conflict of Interest and Corporate Governance
9) Group Processes
10) Mergers and Acquisitions

4. Teaching methods:

Lectures. Consultations. Seminar paper.

Knowledge evaluation (maximum 100 points)

Precondition courses: None

1. Educational goal:

Acquiring the necessary knowledge regarding the functioning of media systems. Students will gain insight into the significance and strength necessary to use a media system for each organization.

2. Educational outcomes (acquired knowledge):

Engineer of management will be able to adequately apply acquired knowledge in their research. You will have the requisite skills and competencies to create new areas of application, media systems in order to increase the effectiveness of business organizations.

3. Course content/structure:

Media Policy, Media Strategy; Media in the function of the integrated economy; Links between media systems, social systems and the audience; Media in Education; Effects of media; Corporate social responsibility of media; Public service; Media regulation; Media convergence; Media Sustainability; Social Media; International decisions, documents, organizations; Impact of new technologies on media; Media positioning; Distribution of media content.

4. Teaching methods:

The method of oral presentation, method calls, work with individuals. Teaching includes lectures and exercises. Evaluation of knowledge is done through an oral exam and seminar work as prerequisites given.

Course:		Strategic Development of Human Resources
Course id:	IMDR52	
Number of ECTS:	14	
Teacher:		Duđak D. Ljubica
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The goal of course is to master the necessary skills to strategically place the development of human resources in an organization, that is, recognizing the link between the success and development of contemporary organizations and the development of its human resources.

2. Educational outcomes (acquired knowledge):

Students will (1) be trained to recognize the importance of strategic human resource development in contemporary organizations, (2) be familiar with the needs and possibilities of the development of different strategies that organizations can define the process of acquiring adequate knowledge of human resources and the development of competitive knowledge, (3) be familiar with the characteristics of the concept of "learning organizations" in modern business and development opportunities and building a "learning organization", (4) able to develop an effective plan for the development of human resources in an organization, and (5) familiar with the operational aspects of the development process, that is, training workers.

3. Course content/structure:

Context of human resource development, human resource management versus human resource management - the debate and the implications for human resource development, strategic basis for the concept of human resource development, strategic human resource development and human resource development strategies, interventions from training to teaching staff as a way of life - Analysis of organizational culture for the development of an effective learning environment, organizational dimensions of human resource development, concept of "learning organization" and the application of modern business, transformational change management from the perspective of human resource development, human resource development role in creating synergies of the organization, developing human resources, building organizational values ??(commitment, business ethics, diversity management), process development and training of employees - operational aspects

4. Teaching methods:

Teaching is done through lectures, study research and consultation during the preparation of the project. The essence of the approach to the teaching of subjects Strategic human resource development in the use and application of theoretical knowledge in the analysis of case studies from real organizations.

1. Educational goal:

Obtaining advanced knowledge in the field of data mining.

2. Educational outcomes (acquired knowledge):

Students will obtain the knowledge and skills that enable them to effectively use applied techniques of artificial intelligence and machine learning for data mining. They will be familiar with various aspects of computers as tools for data mining, detection of structural scheme of the data, presentation and use of discovered knowledge.

3. Course content/structure:

The course will cover the following areas: review of main concepts of data mining, the typical sources and data preparation, decision trees, neural networks, support vector machines, clustering of data, analysis and presentation of data that have temporal and spatial dimension. Theoretical instruction will be accompanied by training in practical use of open source solutions for data mining.

4. Teaching methods:

Auditory and laboratory, seminar paper and oral examination.

Course:		Selected Chapters in Hydraulic Systems
Course id:	IMDR58	
Number of ECTS:	14	
Teacher:		Jocanović T. Mitar
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

Knowledge gained from the subject is used in practice addressing present issues related to the operation and exploitation of hydraulic systems and filtering.

2. Educational outcomes (acquired knowledge):

The student is competent to apply the acquired knowledge to solve problems related to hydraulic systems in practice, and the acquisition of practical skills for independent and team work as well as in scientific research in fields related to hydraulics.

3. Course content/structure:

1.Hydraulic automation systems, 2 Energy efficiency of hydraulic systems. 3.Selected chapters in logical components in hydraulic, 4. Selected chapters in hydraulic power steering, 5 Selected chapters in proportional hydraulics, 6 Impact of variability working regime of physical and chemical properties of fluid, 7 Impact of changes in operation modes to the work of hydraulic components and systems, 8 The issue of exploitation of lubricants in hydraulic systems, 9 Obliteration of fluid power systems, 10. The presence of contaminants in hydraulic system and their impact on performance and service life of components and systems, 11. Problem of filtering, 12. Recycling and the problem of processing used lubricants in the field of hydraulics.

4. Teaching methods:

Lectures: (Co-mentor and student select one or more topics depending on the scope and problems of thematic areas). Consultation. Lectures are delivered in combination with active participation of students. Delivering the theoretical part is followed by the examples to clarify the theoretical part of the curriculum. Part of the teaching activity is carried out through an independent study research in the field of hydraulics. Student`s research work includes active monitoring of primary scientific sources, organization and experiments as well as statistical data processing, numerical simulations, writing a paper about an issue regarding the scientific area of doctoral dissertations.

Precondition courses: None

1. Educational goal:

The goal of course is to master the basic concepts and approaches that allow the definition of the global architecture of the system, the consistency of decision making across the business system, monitoring the flow models whose activities go beyond the limits of functions, business process management and real-time basis for the definition of enterprise business process improvement.

2. Educational outcomes (acquired knowledge):

Students will be able to participate in the creation of different types of organizational and management model of enterprises with the aim of building a complete representation of enterprises, which consists of the definition of the mission, strategy, key performance indicators (KPI), business processes and competencies and their relations to improve synergies within the company and fulfill the mission and vision of an effective and efficient manner. In addition, students will be able to use tools that allow companies to share key information / knowledge to achieve business process coordination and cooperative decision-making, and achieve enterprises integration.

3. Course content/structure:

Structure of enterprises. The functional approach to the organization of business processes. Process approach in the organization of business processes. Methodological approaches to modeling business processes. Business Process Reengineering. Architectures for enterprise integration. CIMOSA and GRAI concepts. ARIS modeling approach and the integration of business processes. Specifics of modeling service organizations and public sector enterprises. PLM as a concept of enterprise integration. Enterprises Interoperability - the basic framework. Integration of information technology in enterprises. Enterprise systems and their integration (ERP, SCM, BPMS). Key performance indicators. Measuring the performance of business processes. Practical examples of the organization, management and integration processes in the enterprise.

4. Teaching methods:

To achieve the set goals of education in the learning process are using a combination of lectures with presentation software solutions and case studies supported by applicative systems for analysis and modeling organizational structures and business processes. Case studies are used to lay the practical basis and show students how to analyze, model and improve business processes in real-life situations

1. Educational goal:

Understanding of eco-products / brands as a modern phenomenon and sustainable ecological imperatives of sustainable development, health security, economic production and environmental improvement. Decision-making in the field of eco-marketing in terms of ecological development of the economy, industry and social development.

2. Educational outcomes (acquired knowledge):

The ability of the optimal management of eco-marketing in terms of environmental engineering, sustainable development and eco-marketing success in all spheres.

3. Course content/structure:

Challenges, strategies and new approaches to eco-marketing. Fitting between traditional and eco / green marketing. Standards, laws, guidelines and recommendations. BAT (Best Available Techniques) and BEP (Best Environmental Practice). Stockholm and Basel Convention. Eco-marketing and environmental engineering, production eco-modification, eco-packaging. The main segments of the integrated sustainable eco-marketing: eco-design, shape, color, eco-positioning. Promotion of organic products and eco-marketing. The main areas of eco marketing: product and productivity in the function of preventing contamination of the environment and the elimination of existing and potential ecological damage. Price of products focused on environmental packaging and organic production. The financial benefit of eco-marketing, fellowship and mutual funds in the eco-marketing. Eco-law. Friendly and eco-oriented marketing activities, substitution of hazardous products with eco-products. Urban metabolism, productivity, flows of hazardous materials, safety and eco-marketing.

4. Teaching methods:

Lectures (mentor with a student chooses one or more modules, depending on the scope of the module). Consultation. Lectures are conducted in combination. Leaving the theoretical part is followed by examples. In addition to lectures are held regularly and consultation. Through study research student, studying scientific journals and other literature, self deepens the material from the lecture. In addition to working with the teacher, student is trained to write your own scientific work.

Course:		Quality abd organisational performance
Course id:	IMDR83	
Number of ECTS:	14	
Teachers:		Beker A. Ivan, Jocanović T. Mitar, Kamberović L. Bato, Milisavljević M. Stevan, Radlovački S. Vladan, Šević D. Dragoljub
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The course is designed as a base for examining the most important outcomes of the quality management system - increase in organizational performance. Students will be introduced to the approaches in research methods of relations between quality management and organizational performance. By observing the nature of relations between these important aspects, students will be trained for the research which are aimed towards effective improvements of in organization

2. Educational outcomes (acquired knowledge):

Upon passing the exam, students will be able to explore the relations between quality management and organizational performance, and to apply existing knowledge in order to achieve effective organization and quality management system improvements. Course provides fundamental knowledge of relationship between quality management and organizational performance dimensions (elements), which serves as guidance of organizational efforts towards effective improvements.

3. Course content/structure:

Quality management system. Quality dimensions. Organizational performance. Examination of the relationship between quality management and organizational performance. Improvements which are based on studies of relationship between quality management and organizational performance. Performance in unfavorable environment.

4. Teaching methods:

Lectures, research work, consultations. The rating is based on the success of the project and an oral exam.

Knowledge evaluation (maximum 100 points)					
Pre-examination obligations	Mandatory	Points	Final exam	Mandatory	Points
Project	Yes	50.00	Oral part of the exam	Yes	50.00

Table 5.2 Course specification

Course:		Data ACQUISITION, ANALYSIS AND INTERPRETATION 1
Course id:	IMDR84	
Number of ECTS:	14	
Teachers:		Pečujlija D. Mladen, Vrgović D. Petar
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The subject aims to enable students to understand many basic concepts, processes, and issues that arise when performing empirical studies in most psychological and managerial disciplines, and thus create a conceptual basis for later studies in facilities that include this type of knowledge.

2. Educational outcomes (acquired knowledge):

Students are trained in-house research design, data collection, data processing, univariate procedures, interpretation of data and preparation of reports on research conducted using the SPSS software package.

3. Course content/structure:

Preparation of research, design research design, data collection, analysis and interpretation of results, and preparation of the report on the investigation. Uzrorkovanje. Levels of measurement (nominal, ordinal, interval, ratio). Design of research tools. Frequency, correlation and factorial research designs. Student t test. Chi-square analysis. Univarjantna analysis of variance (ANOVA). Multivariate analysis of variance (MANOVA). Regression analysis. Within each of the three groups of drawings appear gradually from simpler to more complex types. At the end of the course describes the structure of a standard written report on the investigation. During the course, for illustration shows a large number of (mostly simplified) examples of research in many areas of management.

4. Teaching methods:

Lectures, computer exercises and consultations.

Knowledge evaluation (maximum 100 points)

Pre-examination obligations	Mandatory	Points	Final exam	Mandatory	Points
Computer exercise attendance	Yes	5.00	Oral part of the exam	Yes	30.00

Precondition courses: None

1. Educational goal:

The goal of the course is to enable students to understand the latest approaches in the development of technological and production structures in accordance with their prior knowledge and interests, as well as to introduce research work in this particular field of study.

2. Educational outcomes (acquired knowledge):

The outcome of the subject is the knowledge and student`s ability to understand the issues of effective technological and production structures and engage in research work in this field.

3. Course content/structure:

Changes in the technological and production structures. Approaches in development of technological and production structures. The principles in the development of technological and production structures. Characteristics of technological and production structures. Automation of processes of designing the technological and production structures. Simulation of technological and production structures.

4. Teaching methods:

Lectures: (Mentor and student select one or more modules depending on their volume). Consultation. Lectures are conducted in combination. Presentation of theoretical part is followed by the examples that clarify the theoretical part of the curriculum. In addition to lectures, consultations are held regularly. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures. In addition to working with the teacher, students are trained to write their own scientific and research articles.

Knowledge evaluation (maximum 100 points)

Table 5.2 Course specification

Course:		Advanced topics on Innovation and Entrepreneurship
Course id:	IMDR70	
Number of ECTS:	16	
Teacher:		Borocki V. Jelena
Course status:		Elective

Number of active teaching classes (weekly)

Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The aim of the selected course is to improve and develop theoretical and empirical topics from innovation and entrepreneurship. The students will be able to (1) assess the changes, trends and impacts of different factors from the innovation and entrepreneurship field, to (2) identify strategies and ways how changes were implemented within the organization (product or service company), and (3) to analyze the impact of changes on level of innovation activities and entrepreneurship in existing enterprises (SMEs, companies - multinational, large, industries, institutions supporting entrepreneurship and innovation, et al.). Also, students should understand the impact of a dynamic business environment in creating innovative corporate strategy and innovation management strategies.

2. Educational outcomes (acquired knowledge):

Students who pass the exam will be able to (1) obtain the understanding of advanced research methodologies and approaches in selected areas, (2) compare and analyze the principles and theoretical approaches within several traditional and modern approaches to innovation and entrepreneurship, (3) demonstrate research skills in a process of critical examination all relations between theoretical explanations, methods, research issues and questions and empirical data in the selected area, (4) apply the knowledge and techniques to analyze specific research in the field.

3. Course content/structure:

The nature of entrepreneurship and opportunities - an introductory elements, based on identifying business opportunities in the region, sources of opportunities, active research and discovery, relations and capabilities of the business concept. Market elements of commercialization opportunities - research techniques, assessment of the size of market opportunities. Business ideas and testing the feasibility of the business idea, promotion, creation of business ideas in organizations. Detection of entrepreneurial opportunities and decision models. The concept of innovation - different methods of research; assessement the use of certain models in the changing conditions of the external environment. Business Models - Innovation processes, entrepreneurship, the development of the organization. Analysis of the results of different studies in the field of innovation, entrepreneurship and technology. Identification and selection of key elements of the research. Analysis of different techniques tools and models to gain a competitive advantage through innovation

4. Teaching methods:

Lectures. Consultations. Student independently deepens the subject-matter learned at lectures through his research work while studying scientific journals and other literature. In addition to working with the teacher, students are trained to write their own scientific papers.

Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The aim of the course is that students master advanced approach to project management and specific knowledge necessary for the successful implementation of the project. During the teaching process, students will be introduced to modern techniques and tools integration process, time management, cost, quality, communications, risk and supply, as well as the procedures for the development and improvement of existing approaches, tools and techniques of project management.

2. Educational outcomes (acquired knowledge):

After completing this course, students will be able to manage complex projects, using modern approaches, tools and techniques for scientific research in this field.

3. Course content/structure:

The new project management approaches; Modern techniques and tools of project management;
Project management according to internationally recognized standards software packages for project management, Lean Project Management, Change Management, Development tools and techniques of project management, Agile project management methods.

4. Teaching methods:

Lectures, Auditory Practice, Laboratory Practice and Consultations. Lecturing method is based on the multimedia lectures and practice. During lectures problem frame is presented and facts and theoretical approach is analyzed, while the practice is interactive and practical in the form of laboratory practice. Besides lectures and practice, consultations are held on a regular basis. Lecturing method plans for at least 40% of the time to be devoted to the active participation of students, which includes working in the laboratory and visits to production and service organizations.

1. Educational goal:

Introduction of students in selected field of information management and their preparation for independent research work. Consideration of information technology development perspectives and their applications in engineering management. Studying of actual approaches and methods in research work oriented to advancement of management procedures in business systems and their working processes.

2. Educational outcomes (acquired knowledge):

Introducing of students with modern development trends and approaches in problem solving processes in the field of information management. Students preparation for high-grade and accurate problems recognition and their solving using by scientific and research methods. Development and advancement of students creative component in individual and team work.

3. Course content/structure:

Contemporary information technologies and their development trends. Information technologies as a condition of success in the manager work. Management of information systems development in modern enterprises. Agile approaches in development of software products and systems purposed to support in manager work. Empirical software engineering. Contemporary data base systems and approaches in exploitation of data. Contemporary systems in business resources planning. Fundamentals and development of business intelligence systems. Electronic government systems. Case studies for applications of information technology means in engineering management.

4. Teaching methods:

A student, together with his advisor, select one or more of modules from the subject, dependency of its volume. Lectures are combined (theoretical considerations and analysis of practical examples). Consultations are usual. During of work with professors, a student are preparing himself for writing of scientific articles in selected scientific field.

1. Educational goal:

The course introduces students to research in this area is characterized by an intense and innovative development. Students will become familiar with the development of the area in the past two decades, and the latest research and forecasts about developments in the future. The knowledge acquired will enable students a thorough understanding of the field of quality and logistics, which will form the basis for independent research.

2. Educational outcomes (acquired knowledge):

After completing courses and passing the exam, students will master the existing models developed in the particular area. Students will also gain the ability to create research and to critically analyze existing processes, quality management and logistics.

3. Course content/structure:

Logistics, supply chain management, quality management system, environmental management system, Health and Safety, Continuity of Systems

4. Teaching methods:

Lectures, research work, consultations. The rating is based on the success of the project and an oral exam.

1. Educational goal:

Educational objective: Gaining insight and understanding the complexities of industrial marketing and media engineering, and the necessity of a multidisciplinary approach for problems solving in a given scientific field.

2. Educational outcomes (acquired knowledge):

Gaining abilities for scientific research in the field.

3. Course content/structure:

Fundamentals and present trends in industrial marketing and media engineering. Tendencies in specific behavior of industrial users. Customer involvement and specific customer needs (Customer Co-Creation) in product design and development. Modern holistic approach in industrial marketing management. Modern media application. Media as a function of industrial systems. Quality management and marketing.

4. Teaching methods:

Lectures (mentor with a student chooses one or more modules, depending on the module scope). Consultations. Combined lectures. Theoretical part is followed by adequate examples. Through research study of scientific journals and other literature, student gains further insights in the field. With given mentorship, student is trained for writing scientific paper.

1. Educational goal:

Energy undoubtedly a strong influence on the national and regional economic and social development. This course introduces the chill of the energy flows in the building industry and in order to fully examine the opportunities and needs of their management. Energy efficiency and renewables are a great modern means of which they can make to reduce environmental pollution and production costs. This course covers many areas of energy and gives students the opportunity to get to know the basic tools used to analyze and create efficient energy management at the regional level, business or office building.

2. Educational outcomes (acquired knowledge):

• The acquisition of knowledge in the field of energy menadžmena and training for implementation, implementation and monitoring of the SIST ISO 50001 energy management ENMS.
• Knowledge of the flows of materials and energy production systems and
• Identify solutions for saving energy power systems
• Designing, implementing and monitoring the implementation of energy management.

3. Course content/structure:

Energy in Industry, Energy in Buildings, Energy Efficiency in Energy, Renewable Energy, an integrated policy on energy and the environment; Motivation industry to improve energy efficiency and environmental protection; legal framework for energy management and energy efficiency in the European Union (EU), the concept of energy management, energy management systems, and environmental impacts; Industrial energy systems (industrial steam systems, industrial elektrosistemi, cooling systems, industrial cogeneration); Energy in Buildings (energy requirements of buildings, heat consumption in buildings, thermal protection of buildings, energy infrastructure in buildings, measures to increase energy efficiency in buildings), measurement and verification (M & V) (Determination of energy conservation, monitoring of energy flows, Plan M & V and the summary of the effects Examples of M & V procedures for some parts of the energy system, Manage M & V procedures), design of energy efficient systems and components (effective, optimal and nearly optimal design; concept project, decision matrix, development of the concept; risk in the implementation of energy projects).

4. Teaching methods:

Lectures and workshops. Leaving the theoretical part of the following examples and calculations independent student.
Through study research student in consultation with the supervisor systematically processed following the set subject relevant scientific literature.

Table 5.2 Course specification

Course:	Selected chapters in enterprise's design, organization and control
Course id: IMDR5	
Number of ECTS: 16	
Teachers:	Ćosić P. Ilija, Maksimović M. Rado, Radaković J. Nikola, Tešić M. Zdravko
Course status:	Elective

Number of active teaching classes (weekly)

Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

Acquiring the latest knowledge about design, organization and control methods of enterprises structure, based on group technology, manufacturing cells and the development of production, organizational and control structures with the ability to maintain an independent working existence. Mastering the techniques of applying methods of group approaches in the design, classification and analysis of trends in production and application of these methods and techniques in designing and revitalization of company production, organizational and control structures.

2. Educational outcomes (acquired knowledge):

Necessary knowledge and skills of the students for independent and group research and further research work in the field of design, organizing and control in enterprise. Acquiring skills for project management of construction or rehabilitation of production and organizational structures suitable for management.

3. Course content/structure:

Basics of group technology in manufacturing. Method of design, organization and control based on the classification of objects of production and structures capable of maintaining an independent existence of labor. Methods of design, organization and control based on the FFA, GA, LA, and PFA analysis. Method of design, organization and control based on Lean Principles. Case studies.

4. Teaching methods:

Lectures. Consultations. Seminar paper. Theoretical part of the subject-matter is followed by the examples due to clarify this part of the curriculum. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures.

Knowledge evaluation (maximum 100 points)

1. Educational goal:

The educational goal is to introduce doctoral students in the chosen area of automation that is used in modern engineering industry.

2. Educational outcomes (acquired knowledge):

Outcomes are the knowledge and skills of students in independent and team research and research in the field of automation in industrial engineering.

3. Course content/structure:

A review of research in the fields of sensor, actuator, control systems, robotic systems, system integration, communication protocols, systems for automatic identification.

4. Teaching methods:

Mentor a student chooses one or more areas, depending on the scope of the field. Consultation. Lectures are conducted in combination. Leaving the theoretical part is followed by examples which serve to clarify the theoretical part of the curriculum. In addition to lectures are held regularly and consultation. Through study research student, studying scientific journals and other literature deepens own curriculum with lectures. In addition to working with the student teacher is trained to write your own scientific work in the chosen field.

Precondition courses: None

1. Educational goal:

The course introduces students to research in this area is characterized by an intense and innovative development. Students will become familiar with the development of the area in the past two decades, and the latest research and forecasts about developments in the future. The knowledge acquired will enable students a thorough understanding of the field of quality and logistics, which will form the basis for independent research.

2. Educational outcomes (acquired knowledge):

After completing courses and passing the exam, students will master the existing models developed in the particular area. Students will also gain the ability to create research and to critically analyze existing processes in the field of quality engineering and logistics.

3. Course content/structure:

Reliability, techniques and technologies in maintenance, logistics, supply chains, measuring and control technology

4. Teaching methods:

Lectures, research work, consultations. The rating is based on the success of the project and an oral exam.

Precondition courses: None

1. Educational goal:

Introduction of students in selected field of information, management and communication systems and their preparation for independent research work. Consideration of information technology development perspectives and their applications in industrial systems engineering . Studying of actual approaches and methods in research work oriented to advancement of management procedures in industrial systems and their working processes.

2. Educational outcomes (acquired knowledge):

Introducing of students with modern development trends and approaches in problem solving processes in the field of information, management and communication systems in industry. Students preparation for high-grade and accurate problems recognition and their solving using by scientific and research methods. Development and advancement of students creative component in individual and team work.

3. Course content/structure:

Contemporary information technologies and their development trends. Information technologies as a condition of effectiveness in industrial systems work. Management of information systems development in modern industrial systems. Agile approaches in development of software products and systems purposed to support in manufacturing and production management. Empirical software engineering. Contemporary data base systems and approaches in exploitation of data. Contemporary systems in manufacturing resources planning. Fundamentals and development of business intelligence systems. Case studies for applications of information technology means in industrial systems engineering.

4. Teaching methods:

A student, together with his advisor, select one or more of modules from the subject, dependency of its volume. Lectures are combined (theoretical considerations and analysis of practical examples). Consultations are usual. During of work with professors, a student are preparing himself for writing of scientific articles in selected scientific field.

Precondition courses: None

1. Educational goal:

Overview of situation in the area of the proposed topic for doctoral dissertation based on the scientific literature analysis – books, monographs, papers in referential journals, papers from conference proceedings, available documentation at websites, etc. The objective is to overview the possibilities of the thesis and scientific potential of the topic.

2. Educational outcomes (acquired knowledge):

Study on the potentials of the proposed doctoral dissertation topic, i.e. the systematized knowledge in the area of the research topic for doctoral dissertation, as well as clear directions in further research on the topic.

3. Course content/structure:

Defining the wider area of the doctoral dissertation topic and key motives for research. Overview of literature on the basis of available scientific books, monographs, papers in referential journals, papers from conference proceedings, available documentation at websites, etc. Study on the potentials of the proposed doctoral dissertation topic.

4. Teaching methods:

Teaching is performed as tutorials.

Precondition courses: None

1. Educational goal:

The aim of this course is to master the knowledge necessary for designing and implementing systems for motion control.

2. Educational outcomes (acquired knowledge):

Outcomes of the course are the knowledge that primarily cover the field of linear motion, and include sensors, actuators and control algorithms used for manipulation devices, machines and systems.

3. Course content/structure:

Exploring the possibilities of application of linear motion system with: servopneumatikom, servohidraulikom, DC motors, AC motors, servo motors. Research applications of sensors: proximity, position, pressure, velocity, flow. Exploring possibilities of MEMS as accelerometers, gyroscopes, pressure sensors.

4. Teaching methods:

Mentor and student select one or more modules depending on their volume. Consultation. Lectures are delivered in combination. Delivering the theoretical part is followed by the examples that clarify the theoretical part of the curriculum. In addition to the lectures, consultations are held regularly. While studying scientific journals and other literature student independently deepens subject-matter delivered at lectures. In addition to working with the teacher, students are trained to write their own scientific work.

1. Educational goal:

The aim of this course is to enable students to understand the modern approach of the application of automation in thermal systems and research in this area.

2. Educational outcomes (acquired knowledge):

Outcomes are student`s knowledge and skills for independent and group research and further research work in this area.

3. Course content/structure:

Automation in residential and commercial buildings. Monitoring energy consumption in buildings. Control. The application of automation in education. A part of teaching activity is accomplished through an independent study research in the field of non-industrial automation. Research work includes active monitoring of primary scientific sources, organizing and conducting experiments and statistical data processing as well as writing a paper regarding a topic in the field of study.

4. Teaching methods:

Lectures: (Mentor with the student selects one or more modules depending on its volume). Consultation. Lectures are conducted in combination. Presentation of the theoretical part is followed by the examples that clarify the theoretical part of the curriculum. In addition to the lectures, consultations are held regularly. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures. In addition to working with the teacher, students are trained to write their own scientific and research articles.

Precondition courses

1. Educational goal:

Introduce students to basic concepts of cognitive management, raising awareness of the relevance of cognitive management as applied management discipline, developing awareness of and openness to interdisciplinary cooperation touch with scientific disciplines, exploring the scientific and practical aspects of the problem. Introduction, application and development of standard methods (including experimental testing) and research techniques in management. Introduction to the method of application of psychological knowledge, theory and research to solve problems in practical work.

2. Educational outcomes (acquired knowledge):

Mastering the cognitive principles and regularities of human economic behavior and ways of application of psychological knowledge and principles to the design, editing and predicting economic behavior of both individuals and groups, and understanding the nature of human interaction and psychological characteristics of human psychological processes and economic behavior.

3. Course content/structure:

Introductory considerations. Definition of cognitive management. Predictors of cognitive management. Cognitive management as parallel and sequential process. Terror management theory and cognitive management. Cognitive psychology of learning and management. Attitudes and cognitive management. Values and cognitive management. Emotions and cognitive management. Cognitive development and management. Motivation and cognitive management. Cultural, gender and age aspects of economic behavior. Cognitive management in crisis situations. The concept of justice and cognitive management. Cognitive and tax management. Emotional branding. Changing attitudes: the central and lateral strategies. Connotative and denotative meaning. Hemispheric strategies in information processing and decision making. Psychological aspects of adopting a new economic system. Methods and techniques of research

4. Teaching methods:

Lectures, case studies, practical exercises and consultations.

Precondition courses: None

1. Educational goal:

Goal of the course is to master the basic and advanced skills necessary to analyze, measure and manage the creative potentials of employees in organizations. The course aims to familiarize students with the rules and principles, which are used to optimally manage creative power of all employees in the organization in order to maximize their potential. On the basis of this course competences for research and active management of the creative forces of the whole working organization will be aquired.

2. Educational outcomes (acquired knowledge):

On the basis of goals achieved in the course, it is expected that students will be able to independently design and conduct research processes aimed at obtaining information on the level of creative potential of employees in the organization, about the factors that affect them, as well as their degree of utilization. The outcome of the course will be the students' competences for proper and optimal use of the creative potential of the employees in organizations through a systematic approach, with emphasis on mastering systems of idea management and creative stimulation.

3. Course content/structure:

Thematic sections: Factors and scientific approaches to the concept of creativity, creative potential measurement, researching stimulating and hindering factors of creativity, managing the creative force of employees,idea management systems, open innovation.

4. Teaching methods:

Teaching is done interactively, with the active participation of students in the teaching process and with organizing empyrical research of the observed phenomena.

1. Educational goal:

The goal of the course is to enable students to learn, develop and design different organizational structures necessary to plan, organize, lead and control processes.

2. Educational outcomes (acquired knowledge):

Students will obtain knowledge and competencies for analyzing processes, different types of organizational structures and for resolving practical problems in ant type of the company.

3. Course content/structure:

Vision, mission, goals, objectives and politics of the company; stakeholders, processes and their relations inside the company; different flows in the company; types of organizational structures; how to design effective organizational structure; organizational changes

4. Teaching methods:

Lectures are auditory with theoretical treatment of the required number of case studies. Practice include auditory introduction to issues in focus, interactive processing of case studies and specific class projects due to use the acquired knowledge for real organizational structure design. Individual work - case study of one company from environment.

1. Educational goal:

The objective of the course is to train students for basic and applied research work in the field of raster technology and image processing and further enhance their prospects for the use of resources and tools based on these technologies in industrial engineering and management.

2. Educational outcomes (acquired knowledge):

Opening new horizons of research in this area and define new areas of application of the underlying technology in industrial engineering and management. Practical means and tools to master the subject area and their application in research.

3. Course content/structure:

Fundamentals and mathematical basis of raster technology. Principles and means of digitization of documents and images. Structure and form of document in raster presentation. Raster presentation - fields and methodology. Recognition based on raster presentations. Cryptology. Processing digital documents and images. Principles and Methods of Image Processing. Pattern vectorization of raster presentation. Entity recognition. Application in media, industry and military technology. Research in the field of machine and robo-vision.

4. Teaching methods:

Teaching activity depends on the number of listeners, i.e. mentor or frontal approach.
During the course, students are required to prepare a seminar paper and its defense.

1. Educational goal:

Development of multicriteria review and systematic approach to using computer supported technologies in developing and designing new processes and reengineering existing products. Introducing listeners in research aimed at developing and implementing effective production processes and procedures based on computer integration of manufacturing, Rapid Prototyping and Rapid Manufacturing concepts.

2. Educational outcomes (acquired knowledge):

Listeners need to acquire certain knowledge and skills in computer aided modeling and redesign of industrial products, engineering analysis based on the digital product model, a highly productive design and modern approaches to documenting and archiving research and development results. As part of the subject, the audience will developed a clear vision of future product development and engineering design, and industrial production as a whole.

3. Course content/structure:

Industrial product as a technical system. Form, structure and metrics as the basic definition of the product. Engineering design and information technology to support development and product design. Computer aided modeling: principles, methods and tools. CSG and B-Rep model of the principles of building components. Sweeping Method. The principles of automated formation of higher-level application. The procedures and methods of computer aided engineering analysis. Construction supported by software tools. Documenting and archiving - concept and functions of digital archives. Design procedures in the production and assembly. Computer integration of manufacturing, fundamentals of CIM. Rapid Prototyping and Rapid Manufacturing methods and processes in modern industrial production.

4. Teaching methods:

Frontal approach in teaching activity; mentor approach in the case of small number of students.
During the course, students are required to prepare a seminar paper and its defense.

Knowledge evaluation (maximum 100 points)

Pre-examination obligations	Mandatory	Points	Final exam	Mandatory	Points

1. Educational goal:

To achieve the set goals of education in the learning process using a combination of lectures, with presentation software solutions, and case studies supported software products for the implementation of a system for managing work processes. Case studies are used to lay the practical basis and show students how to apply different technologies in realistic industrial enterprises.

2. Educational outcomes (acquired knowledge):

Students will be able to participate in the creation of diverse and non-standard systems management that are incurred as requirements of different types of organizational structures and production companies. In addition, students will be able to apply the theoretical methods and techniques developed in the case studies show that the solutions to achieve business process coordination and cooperative decision-making, and how to manage the process of integration in the enterprise.

3. Course content/structure:

Structure of enterprises. Approached in the organization of business and production processes of enterprises. Specifics of the service organization's system and public sector enterprises Process approach in setting up the organizational structure. Production structure of the company. Access OPT - Optimum production technology. Approach - PBC - Management at equal intervals. Management in terms of group technology. Controls structure in LEAN manufacturing. Running a virtual system products. Information and communication technologies for the management of work processes. Implementation of SAP system in the management and production management. Practical examples of the organization, management and integration processes in the enterprise.

4. Teaching methods:

To achieve the set goals of education in the learning process using a combination of lectures, with presentation software solutions, and case studies supported software products for the implementation of a system for managing work processes. Case studies are used to lay the practical basis and show students how to apply different technologies in realistic industrial enterprises.

Course:	Application of Information and Satellite Technologies in Risk Management
Course id: IMDR45	
Number of ECTS: 14	
Teacher:	Popov B. Srđan
Course status:	Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The aim of this course is to enable students to understand the modern approach in the application of information and satellite technology in the field of risk management.

2. Educational outcomes (acquired knowledge):

The course outcomes are student`s knowledge and skills for independent and group research and research work in this area.

3. Course content/structure:

The reasons and the need for application of information and satellite technology. The present situation in the field of satellite technology. The connection between information and satellite technology. Modern software tools for the application of technology in risk management. Examples of application of technology in all phases of the risk management cycle.

4. Teaching methods:

Lectures. Consultation. Lectures are delivered in combination (traditional instruction and distance learning). Delivering the theoretical part is followed by the examples that clarify the theoretical part of the curriculum. Consultations are held regularly in addition to lectures. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures. In addition to working with the teacher, students are trained to write their own scientific and research articles.

Precondition courses: None

1. Educational goal:

The aim of this course is to enable students to understand the latest theoretical and practical knowledge in the narrow field of financial risks (including financial engineering) and the introduction of the research work in this area.

2. Educational outcomes (acquired knowledge):

The course outcome is student`s knowledge and training for independent and group research and research work in the management of financial risks (including financial engineering).

3. Course content/structure:

Forward (forward) and futures (futures) contracts and hedging (hedging) exposure to financial risks; price estimate options (option pricing) using a binomial and Black-Scholes model of dynamic hedging; indicators of financial risk (Value-at-Risk, Cashflow-at-Riski.td); SWAPS and their use, and financial engineering (exotic derivatives and related financial products).

4. Teaching methods:

Lectures. Consultations. Seminar paper.

Table 5.2 Course specification

Course:		Media Research
Course id:	IMDR50	
Number of ECTS:	14	
Teacher:		Radenković B. Vladimir
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

Acquiring the necessary knowledge in the field of research. Students will become familiar with the strategies and tools for media research, as well as with all relevant conditions in which modern organizations operate, and which have significant implications for media research results that the organization are using to improve the implementation of their communication goals within overall business objectives.

2. Educational outcomes (acquired knowledge):

Application of knowledge in research on filling specific organizational requirements. Engineering Management will be able to apply their research skills in order to get the desired information relevant to the implementation of the communication and media plan in any organization. Also, the improvement of their competence there is a possibility of opening new areas of application of all aspects of media research.

3. Course content/structure:

Investigation of the media and society; profit and objectives of media organizations in the media industry and market, media relations and environment, media and the public; Media changes in the direction of individualization and multiplication of consumer choice and audience fragmentation, modernization, globalization and commercialization of the media, Selected Topics in Media Control; Quantitative and qualitative measurement of diversity, balance, social benefits and production values of media content; Comparative study on the interaction of media, technology and communication, subjective and objective measures to assess the quality of picture and sound.

4. Teaching methods:

Classes are taught through verbal lectures and audio-visual exercises, with the introduction of the theoretical background of media research and learning based on practical examples. Testing knowledge is done through the development of the paper, which is obligation before final exam, and final oral examination.

Precondition courses: None

1. Educational goal:

The behavior of the employees is the most important factor of success. The complexity of studying the employees` behavior is conditioned by the fact that organizational behavior as a function of organizational culture, structure, personal characteristics, value and economic context on which the organization is based. Employed as carriers of human capital, their knowledge, skills, motivation, experience, form the basis of the development of the organization. The aim of this course is to introduce students to the basic laws of organizational behavior, and factors that determine it. Another aim is to master knowledge and skills important for directing, managing and developing desired organizational behavior.

2. Educational outcomes (acquired knowledge):

Students learn about the basic laws of organizational behavior, determinants, master the tools to diagnose current and desired behavior, and models of development and improvements in their results.

3. Course content/structure:

1. Organizational design and employees` behavior
2. Organizational culture
3. Staff - abilities, skills, knowledge
4. Organizational Communication
5. Team performance
6. Management Styles
7. Stress
8. Development of organizational behavior

4. Teaching methods:

Lectures and exercises

Precondition courses: None

1. Educational goal:

The aim of this course is to enable students to master and learn about the latest trends in the life insurance industry with special focus on new products and the European Union directives relating to life insurance and their implementation in practice of insurance companies.

2. Educational outcomes (acquired knowledge):

The reasons and the need for signing a life insurance. State life insurance in our country and the world. The possibility of implementing new life insurance contract and directives of the European Union in Serbia.

3. Course content/structure:

-The new life insurance contracts that are used in most developed countries, and still have no application or application is still expected in the market of life insurance in Serbia
-Contract-saving (savings), unit link, risk life insurance, life insurance with additional risk in case of serious illness
-EU Directive relating to life insurance and that Serbia will be obliged to apply as a condition for joining the European Union
-Contemporary models of life insurance commition as a precondition for the development of life insurance procedure applied in most developed countries-implementation of ISO procedures and instructions in the branch of life insurance
-Bank assurance in the life insurance industry
-New trends in the voluntary pension insurance

4. Teaching methods:

Lectures (traditional and distance learning). Consultation. Introduction to the theoretical concepts of insurance policy in the most developed countries worldwide. Students research work, scientific journals and other literature that enable them to write their own scientific papers with the assistance of their teacher.

1. Educational goal:

The acquisition of advanced knowledge in the field of computer vision and extraction of information from multimedia contents (pictures and videos).

2. Educational outcomes (acquired knowledge):

Students will obtain the knowledge and skills that enable them to effectively apply the techniques of using images and video, artificial intelligence and machine learning to extract information from multimedia content. They will be introduced to different problems in the domain computer vision and basic techniques used to solve them.

3. Course content/structure:

The course will cover the following areas: techniques for coding and storing pictures and videos, image segmentation based on texture and color, object detection, classification, texture, detection of moving objects, tracking moving objects, detection of interesting behavior of objects and subjects. Theoretical classes will be complemented by hand-on training in the use of open source computer vision software to solve practical computer-vision problems.

4. Teaching methods:

Auditory and laboratory, seminar paper and oral exam.

1. Educational goal:

The aim of the course is obtaining current knowledge and understanding of contemporary approach in the field of traceability and introduction into research issues in this area.

2. Educational outcomes (acquired knowledge):

Outcomes of the course are the knowledge that enables systematic traceability of different types of products and skills for independent and group research and advanced research work in this area.

3. Course content/structure:

Traceability of products. Introduction to the problem. Aspects of traceability. Traceability in the food industry. Environmental aspects - recycling. Modeling process and system of traceability. Standards of traceability. Technologies applied in product traceability. Infrastructure for access to information about the product. Tracking products in real time. Research trends in product traceability. Research of social and legal aspects of traceability. Case studies. Experimental studies in the laboratory.

4. Teaching methods:

Lectures: (Mentor with the student selects one or more modules depending on the volume.) Consultation. Lectures are delivered in combination. Theoretical part of the subject-matter is followed by examples due to clarify this part of the curriculum. Lectures and consultations are held regularly. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures. In addition to working with the teacher, students are trained to write their own scientific and research articles.

Course:		Project Approach in Effective Systems
Course id:	IMDR59	
Number of ECTS:	14	
Teacher:		Palčič -. Iztok
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

Acquiring knowledge about (1) project approach and effective systems, (2) theoretical bases in the area of leadership and project management, (3) current state in the subject area of project management, (4) current research and directions of further development and (5) intelligent systems supported through the establishment of Project Management. The aim is to assess the difference between leadership and management in the subject area, as well as understanding the concept of project readiness.

2. Educational outcomes (acquired knowledge):

Based on the philosophy of the project approach students will understand and be capable to improve working processes in the area of the project activity. According to the theoretical basis and situation in the domain of supremacy students will define the research area and contribute the selected trends in the scientific field of interest as well as advance the development of knowledge on managing projects in an unstable situation. Participants will be prepared to influence the development of project approach to effective systems.

3. Course content/structure:

Links between project management leadership (PML) and scientific approaches in the effective system (ES). Philosophy of the project and ES. Theoretical support in PML. Projects as a heritage of mankind. Philosophy of the organization, strategy and project success. Links between project success and project readiness of ES. The organizational aspects of project management. Scientific approach in PML discipline. The situation in the subject area according to the relevant scientific and professional sources. Leading researchers and their work. Areas explored since the PML became a scientific discipline. Approaches in the development and implementation of projects based on scientific knowledge. Current research in the field of PML (2000 - 2010). The project strategy. Dimensions of project success. Comparison between traditional and modern approaches. The importance of interest groups. Office, as a central unit, for project management. Access to "thinking beyond the boundaries of traditional values in project management". Ethics in PML. Beyond the boundaries of traditional PML. The project approach in manufacturing and product life cycle. Intelligent ES and project approach.

4. Teaching methods:

Lectures. Consultations. Seminar paper. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures.

1. Educational goal:

Acquiring the latest knowledge on the most important characteristics of company structure and their interconnectedness, as well as their impact on the other characteristics. Mastering techniques for the development of enterprise structure of low complexity and high flexibility.

2. Educational outcomes (acquired knowledge):

Student`s basic knowledge and skills for independent and group research and research in the field of organizational structure. Understanding crucial points of the relationship between the elements of company structure. Acquiring skills for project management of company construction or rehabilitation.

3. Course content/structure:

The complexity of manufacturing / service, organizational and management structure of companies, flexibility of production / service, organizational and management structure of companies. Interrelation of characteristics of complexity and flexibility of company structure. Company structure design with the most favorable ratio of complexity and flexibility. Case studies.

4. Teaching methods:

Lectures. Consultations. Seminar paper. Theoretical part of subject-matter is followed by the examples due to clarify this part of the curriculum. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures.

1. Educational goal:

Acquiring the latest knowledge about the requirements to create an innovative company and possible differences between production and service companies. Identifying the impact of dynamic business environment to create innovative corporate strategy.

2. Educational outcomes (acquired knowledge):

Learning outcomes are required knowledge and skills of the students for independent and group research and further research work in this area.

3. Course content/structure:

Innovation - the basic concepts, strategies, innovations, innovative activities. Innovative organization - creating the basic preconditions, characteristics of innovative enterprise - management style, organizational structure, process innovation, staff training, creating a climate for encouraging innovative activities, characteristics of the basic models of measuring innovation enterprise, innovation in the region, differences in innovative activities of manufacturing and service companies.

4. Teaching methods:

Lectures. Consultation. Seminar paper. Examples from practice. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures. Theoretical part of the subject-matter is followed by the examples due to clarify this part of the curriculum. In addition to working with the teacher, students are trained to write their own scientific and research articles.

Course:		Enterprise Business Process Integration
Course id:	IMDR62	
Number of ECTS:	14	
Teachers:		Šormaz N. Dušan, Tešić M. Zdravko
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The aim of this course is acquiring knowledge on different approaches to the integration of business functions in manufacturing and service companies. Mastering the procedures, methods and techniques of business process integration with the aim of business system management - business.

2. Educational outcomes (acquired knowledge):

Gaining knowledge that will enable students to observe the company as a system of integrated business processes. Understanding the core functions of integration and needs of the company. Acquiring knowledge of automated systems to manage business and production processes in business system - company.

3. Course content/structure:

3. Course content/structure:
Enterprise organization and management in the terms of integrated business processes within the company. IIS access to the integration of company`s functions. ERP concept of Integrated Business Management. LEAN concept of company integration. Business Process Management - BPM approach to business process integration. Case studies (SAP, ORACLE, BAAN).

4. Teaching methods:

Compulsory number of lectures with examples from the above approach. Consultations are held regularly during and after the lectures. Seminar paper written on the basis of required reading and at least three papers published in journals from the SCI list. Through the study research work, seminar paper, scientific journals and other literature student deepens the knowledge acquired at the lectures. Application of obtained knowledge on writing scientific paper.

Precondition courses: None

1. Educational goal:

Acquiring the latest knowledge on key principles and the principles of entrepreneurship in innovative economy and the main characteristics of organizational development. Knowledge of the latest trends and key changes and concepts of organizational development and creating strategic plan of company development.

2. Educational outcomes (acquired knowledge):

Necessary knowledge and skills of the students for independent and group research and further research work in this area. Acquiring the ability to work independently in the company and / or institutions to support innovative enterprises, understand the core technology development, types and importance of certain institutions to support high-tech entrepreneurship.

3. Course content/structure:

Basic concepts and trends in modern business - impact of changes; role of corporate entrepreneurship to achieve higher levels of innovative activity in the enterprise; impact on the level of enterprise, characteristics of an innovative economy, strategic planning and entrepreneurship; stages of organizational development, creation of strategic plan of enterprise development and its application in unstable conditions. Characteristics of high-tech entrepreneurship, "technopreneurship. Problems in organizational development and ways of their solving - organizational development pyramid.

4. Teaching methods:

Lectures. Consultation. Seminar paper. Examples from practice. Through the study research work, scientific journals and other literature student independently broadens the knowledge presented at lectures. Theoretical part of the subject-matter is followed by the examples due to clarify this part of the curriculum. Table 5.2 Course specification

Course:		Managerial decision-making
Course id:	IMDR66	
Number of ECTS:	14	
Teacher:		Mitrović M. Slavica
Course status:		Elective

Number of active teaching classes (weekly)

Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The following are the objectives of the course Managerial decision-making: 1) to master the basic knowledge in the area of ??managerial decision-making in the industrial system; 2) to introduce students to methods and techniques of making managerial business decisions; 3) to train students in applying these tools and techniques; and 4) to introduce students with the rules of decision-making, factors of influence, as well as properties of decision makers. The purpose of the course is to provide students of management with competencies that will enable them to apply the basic principles and approaches for making functional managerial decisions in industrial systems.

2. Educational outcomes (acquired knowledge):

Students attending the subject of Managerial decision-making and passing the exam are enabled for the following: 1) applying the principles and approaches towards making functional decisions; and 2) using decision-making software for making the business system more successful. The student of management acquires competence in applying the principles and use of software for decision making, as the basis for improving the quality of industrial systems.

3. Course content/structure:

Introduction to managerial decision making; The process of strategic decision-making (good and bad decisions, Types of decision); Factors and stages of decision-making (constraints, environments, methods of decision-making); The context and framework of strategic decision-making, methods of growth in new markets; Personal factors of decision-making (knowledge, skills, and personality traits); Managerial / entrepreneurial decision-making (management style / decision-making style, responsibility and authority); Implementation of business decisions (resources required for the implementation of decisions, their monitoring and evaluation); Models of strategic managerial decision-making (Functional decision making); Decision-making software in business systems: Doctus, Excel Solver; Methods and techniques of strategic decision-making: Structured conflict, Delphi technique, electronic brainstorming, nominal group technique.

4. Teaching methods:

Lectures are presented with the aid of computers, consultation, and seminar papers - presentations.

Knowledge evaluation (maximum 100 points)

Course:		Selected Chapters in Product Lifecycle Management
Course id:	IMDR67	
Number of ECTS:	14	
Teacher:		Anišić M. Zoran
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The goal of the course is mastering the skills required to effectively manage product lifecycle in the conditions of constantly changing functional requirements of the market, production system as well as environmental requirements during its service. Learning about the concept and factors of product lifecycle management (PLM) through building basic structures that ensure the effective creation, sharing and storing information about the product as well as its application in modern strategy of product management.

2. Educational outcomes (acquired knowledge):

Outcomes of the course are acquired knowledge about the structure of the product and family architecture of related products. The acquired engineering knowledge related to each of the phases of the lifecycle under the integrated software for monitoring and management.

3. Course content/structure:

The principles of integrated product development process. Product lifecycle, planning and management. Definition of the product. Specifications and market position of products. Structural Scheme for product and communication between the parts, components and product systems. Presentation and management of product family and product line. Functional requirements and decomposition through the application of Mass Customization and Open Innovation strategies. Product configurator.

4. Teaching methods:

Lectures. Consultations. Seminar paper.

Course:		Business Communication in Effective Systems
Course id:	IMDR68	
Number of ECTS:	14	
Teacher:		Lalić S. Danijela
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The goal is that students who study effective communication systems become familiar with main issues of business communication and thus, through the combination of theoretical background and current research work obtain basic knowledge for further research in the subject field and to link the current situation with the situation in real effective business systems.

2. Educational outcomes (acquired knowledge):

Students will master the issues of effective business communication, as well as relevant sources of the latest achievements in this area and thus, be prepared to approach research problems related to business communication in unstable conditions.

3. Course content/structure:

1. Introduction: Effective systems - effective (internal and external) communication 10%
2. Theoretical background 30%
3. Current situation in the field of research 10%
4. Current research, "open" questions and examples of good practice 30%
5. Presentation of independent research work 20%

4. Teaching methods:

Auditory and research work (with emphasis on research techniques on the Internet)

Table 5.2 Course specification

Course:		Selected chapters from energy efficiency of compressed air systems
Course id:	IMDR86	
Number of ECTS:	14	
Teachers:		Šešlija D. Dragan, Dudić P. Slobodan
Course status:		Elective

Number of active teaching classes (weekly)

Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The educational goal is to deepen the knowledge of doctoral students in the field of energy efficiency of compressed air automated systems and, in that sense, to became familiar with advanced pneumatic control systems, which is used in modern compressed air systems.

2. Educational outcomes (acquired knowledge):

Learning outcomes are the knowledge and skills of students in independent and team scientific and research work in the field of energy efficiency of compressed air.

3. Course content/structure:

Pneumatic control systems with the end position control, pneumatic control systems with stops between the final position, modeling of components (compressed air cylinders, control valves, ...), simulation models of pneumatic components, the application and effectiveness of different control techniques (P, I , D, PI, PID) on energy efficiency, Fuzzy regulation and energy efficiency of compressed air systems, Sliding mode and the energy efficiency of compressed air systems, Servopneumatic control and energy efficiency of compressed air systems, application of PWM control to increase the energy efficiency of compressed air systems, application of PCM control to increase the energy efficiency of compressed air systems, application of PNM control to increase the energy efficiency of compressed air systems, Influence of compressed air quality on energy efficiency, Non-conventional pneumatic actuators influence on energy efficiency, Pneumatic systems with closed circuits, Energy efficiency of complex (with pneumatic and / or hydraulic components) robotic cells.

4. Teaching methods:

Lectures are conducted in a combined way. Leacturing of the theoretical part is followed by examples which serve to clarify the theoretical part of the curriculum. In addition to the lectures, consultations are held regularly. Through study research student, studying scientific journals and other literature and conducting experiments, independently deepens the subject. In addition to working with the student teacher is trained to write his own scientific work in the chosen field.

Table 5.2 Course specification

Course:		Financial engineering of public sector
Course id:	IMDR87	
Number of ECTS:	14	
Teachers:		Dobromirov P. Dušan, Radišić M. Mladen
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

Enabling students to adopt the principles of functioning of public institutions and to identify the most important trends of the application of modern engineering tools in the public sector, with the introduction to the key factors that determine national fiscal structure. The most important educational goals are to understand the basic concepts of defining the mobilization and disbursement of public resources; the acquisition of knowledge in the area of ??the company's relations to the public sector and benefits from the public sector; acquiring knowledge about the application of modern engineering tools in the public sector.

2. Educational outcomes (acquired knowledge):

Students will gain knowledge about the role and importance of public sector functioning for enterprises and industrial systems and understand the methods of analysis and decision-making in the public sector, as well as public sector regulation forms. The knowledge gained helps students understand the basic concepts of public sector management and participate in defining the relationship of the companies to the public sector.

3. Course content/structure:

The role and importance of the public sector. Public sector organization models. Public sector management. Defining the concepts of mobilization and disbursement of public resources. Relationships between the various government levels. The application of modern engineering tools in the public sector.

4. Teaching methods:

Lectures. Consultations. Essay.

Knowledge evaluation (maximum 100 points)

Precondition courses: None

1. Educational goal:

Teaching enables students to master the complete process of planning and implementing cost structure of the investment cycle. The most important educational objectives relating to the preparation of students and adapting to new trends in the management of the investment cycle cost structure (and implementation plan) that include development of various projects of this type.

2. Educational outcomes (acquired knowledge):

Students will gain knowledge in the planning and implementation of cost structure of the investment cycle and learn about the latest trends.

3. Course content/structure:

Analysis of the necessary conditions for investment. The structure of the investment (a new building or machinery, technology, extension, expansion, investment and maintenance). Analysis of the market-defining programs. Return on investment budget and budget impact to the business (loans, profits, increased employment and the like.). Source documentation for the decision (investment initiatives, programs, business plan), sources of funding (own funds, loans, banks, funds). Planning investment flow. Documentation and approval (approval) for investment. Legislation and EU regulations. The realization of investment, contracting, performance, download. Activate investment.

4. Teaching methods:

Lectures. Consultation. Essay.

Table 5.2 Course specification

Course:		Controlling and Internal Audit in Corporate Governance.
Course id:	IMDR89	
Number of ECTS:	14	
Teachers:		Perović I. Veselin, Nerandžić B. Branislav
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The aim of the course is to teach students about future PhD engineers with modern corporate governance instruments and instruments of implementation of modern management model of corporate governance. The basic knowledge and understanding of internal auditing and controlling, mainly audits of corporations in order to achieve the strategic goals of the organization and the industrial system and reduce business risks to achieve it.

2. Educational outcomes (acquired knowledge):

Acquiring knowledge and skills necessary for the implementation of standards, procedures and internal control models of companies and other organizations. Knowledge of the practical application of tools and techniques of controlling business analysis reports in a company or other organization. Students will be able to: identify strategic components of control and internal audit, using models and tools for the analysis of controlling in businesses and organizations, draw conclusions, propose and compare different strategies that shape the reports and recommendations to the shareholders and management of the company, to participate in the application strategy to position the company with highly skilled engineers who are located at the position of analysts by enhancing performance measurement systems controlling companies and organizations involved in scientific research teams of enterprise management tools.

3. Course content/structure:

Strategic and operational Controlling Instruments. Controlling the preparation of business reports; Preparations for the analysis of business reports, check the operation of the information system of internal control, audit of financial statements; Wider rating company's solvency, financial and non-financial ratios, grade of integration of business processes; Problems surface for analysis, assessment of business model rizikas , methods of analysis, internal audit, and international standards, planning and stages of internal and operational auditing, internal audit role in the creation of the management of business risks.

4. Teaching methods:

Lectures using audiovisual equipment. Consultation. Lectures by experienced executives in part or whole enterprises function in the role of guest lecturers.

1. Educational goal:

The aim of this course implies completion and integration of component of strategic thinking necessary to PhD candidates - engineers who takes positions within the functions of finance, accounting, planning, control and financial reporting. Acquiring basic knowledge and understanding of accounting information as a management tool, in order to achieve the strategic goal of the industrial system and organization as well as reducing business risks in achieving strategic goal.

2. Educational outcomes (acquired knowledge):

Acquiring knowledge and skills needed to implement standards, procedures and models for the evaluation of company's solvency in order to integrate successfully all functions in the company. Knowledge needed for the practical application of tools and techniques for strategic management accounting in the company and other organizations. Students are qualified to identify strategically components of information base of accounting system, use models and tools in order to analyze competition in the company and other organizations, make conclusions, propose and compare different strategies, create reports and recommendations for capital owners and management, participate in the application of strategy as an engineer who holds PhD and takes positions of scientific worker or analyst through the improvement of system of performance measurement of the company and other organizations.

3. Course content/structure:

The structure of strategic management accounting. Making of financial and business reports; Analysis of business reports of competitors from the point of the achievement of the strategic objectives of the company or corporation. Monitoring the operation of information systems and system of internal controls of the organization; Audit of financial statements; Evaluation of the company's solvency; Assessment of the integration of business processes; Analysis of the financial result in terms of strategic corporate objectives; Analysis of financial situation; Analysis of the production factors; Analysis of the production operations; Analysis of the consolidated business reports of multinational corporations; Transfer pricing in multidivisional business systems.

4. Teaching methods:

Lecturers use audiovisual equipment. Case studies. Consultation. Occasionally lecturers are experienced executives from the companies in the role of guest lecturers

Table 5.2 Course specification

Course:		Product Family Development and Product Configurators
Course id:	IMDR91	
Number of ECTS:	14	
Teacher:		Anišić M. Zoran
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

Mastering the development of modular product family architecture suitable for creation of a large number of product variants, according to individual customer requirements. Also, product configurator design able to connect customer requirements with functional characteristics of the product.

2. Educational outcomes (acquired knowledge):

After completing and passing the exam, students are able to design the architecture of the product and the production program that is suitable for the configuration to suit individual customer requirements. Students are also able to design the structure of the product configurator according to the required depth and width of customization.

3. Course content/structure:

Basics of Mass Customization strategy. Product family structure and development of structural scheme for a production programme. Linking consumer demands, attributes and their values ??to functional characteristics of a product. Determination of width and depth of customization. Different types configurators. The structure and design of a product configurator. Various case studies of commercial configurators.

4. Teaching methods:

Lectures are auditory, followed by appropriate slides, while excercises are performing in small groups mostly auditory, but partly in a computer laboratory.

Knowledge evaluation (maximum 100 points)

1. Educational goal:

The goal of the course is mastering the advanced techniques of exploratory and normative techniques in the function of technological and business forecasting.

2. Educational outcomes (acquired knowledge):

After completing the course and passing the exam, the student is able to use the advanced techniques of business and technology forecasting, which can be quantitative or qualitative. Students will be able to fully implement forecasting in real production and service systems.

3. Course content/structure:

Parameter selection and data collection. Data processing. The choice of forecasting methods. Exploratory methods: time series analysis, writing, morphological analysis. Normative methods: PATTERN methods and significance tree. Principles of prediction. Interpretation of forecasting results.

4. Teaching methods:

The lectures are auditory providing necessary theoretical background, while the exercises include examples of work assignments which are related to practical problems in the design of future technological trends.

Course:		Virtual Enterprises and Collaborative Systems
Course id:	IMDR93	
Number of ECTS:	14	
Teachers:		Herakovič S. Niko, Lazarević M. Milovan, Šormaz N. Dušan
Course status:		Elective

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The course teaches the students the basic knowledge necessary to understand and analyze the latest approach in the development of virtual enterprises and collaborative systems and their organization and management. In addition, students will learn about the latest research in this area and will be trained for independent research in the subject area.

2. Educational outcomes (acquired knowledge):

After completing the course and passing the exam, students will be able to independently design and analyze virtual enterprise, as well as conducting research using valid scientific methods, with the aim of improving and optimizing existing virtual enterprises.

3. Course content/structure:

Introduction to the concept of virtual enterprise. Virtual environment. Agile virtual enterprise. The integration of virtual enterprises. Knowledge management in virtual enterprises. The concept of digital factory and digital production. Distributed production in virtual enterprises. The formation of virtual enterprise. Cooperative work. Distributed manufacturing companies and engineering teams. Production planning. Scheduling. Automation and Control. Simulations. Digital engineering. Collaborative design at an early stage. Work processes and communication systems. The human and social aspects of virtual enterprise.

4. Teaching methods:

Lectures: (Mentor with the student chooses one or more modules, depending on the scope of the module). Consultation. Lectures are conducted in combination. Leaving the theoretical part, followed by examples which serve to clarify the theoretical part of the curriculum. In addition to lectures, are held regularly consultation. Through study research student, studying scientific journals and other literature deepens own curriculum with lectures. In addition to working with the teachers, the students are trained to write your own scientific work.

Number of active teaching classes (weekly)				
Lectures:	Practical classes:	Other teaching types:	Study research work:	Other classes:
5	0	0	4	0

Precondition courses: None

1. Educational goal:

The course introduces students to research in the field of environmental management system in terms of relations with the logistics processes, processes related to the quality management system, hydraulic systems and processes related to customer relationship. Students will become familiar with the development of the area in the past two decades, and the latest research and forecasts about developments in the future. The knowledge acquired will enable students a thorough understanding of the field of the system of environmental management, which will form the basis for independent research.

2. Educational outcomes (acquired knowledge):

After completing courses and passing the exam, students will learn existing models of environmental management system from the standpoint of quality management systems, hydraulic systems, processes related to customer relationship, and logistics processes. Students will also learn the ability to create research related to the area and to critically analyze existing processes of environmental management system in the monitored enterprise.

3. Course content/structure:

Course covers the development of the concept of sustainable development, global environmental problems, causes and consequences of environmental degradation, advanced principles of strategy and policy for sustainable development, environmental risk management principles.

4. Teaching methods:

Classes include lectures on the analysis of the examples, and the choice of different strategies and assessing the strategies to protect the environment. Students create project and present it to other students making the group after which a debate is realised. The exam consists of two parts: theory and tasks.

1. Educational goal:

Modern business characterized by multidisciplinarity, the use of modern technology and the increased intensity of changes, therefore it is necessary to train the participants to manage change through projects and train them for coordinating and directing the project from a variety of functions that businesses and projects are implemented by a number of companies in accordance with the requirements set and defined goals. Sustainability in the global market depends on the success of the company to manage changes through a series of multidisciplinary projects implemented by the internal and external environment so that it can be said that the modern form of management - project management. Process quality, effectiveness and efficiency of operations caused by the successful implementation of several projects using the knowledge, tools and techniques to manage a portfolio of projects to internal and external level. The main educational objective of this course is to enable students to succe

2. Educational outcomes (acquired knowledge):

After completing and passing the course, students are able to: identify the needs of stakeholders (users, corporate, organizations, institutions ...) to launch its portfolio of projects, perform the necessary analysis to determine the feasibility and viability of the projects, accurately define and agree on project ideas, define , plan and integrate the activities of multiple projects, analyzing and allocating the necessary resources in accordance with project priorities, and analyze the costs of the project, in collaboration with other members of the team involved in the implementation and control of the project portfolio, to the final results of the activities of the project to provide use and design documentation and the experience archive.

3. Course content/structure:

The integration process; Joint action of companies; Changes in the company; Managing change and managing a portfolio of projects; Standards and methodologies of project management; Requirements analysis; Methods and techniques; Portfolio preparation and initiating projects; Planning and integration of activities and resources for multiple projects; Project costs; Quality Management; Managing, implementation and coordination; Design documentation, Establishing control system of project portfolio; Project resources and procurement; Closure projects.

4. Teaching methods:

Multimedia lectures and exercises with examples of projects portfolio and explanation of the specific methods and techniques. Lectures in part by experienced project managers in the role of guest lecturers. In the exercises to encourage small group work, students are trained to implement project portfolio management methodology on specific examples of the application of engineering methods and techniques. Exercises are performed by a computer in a laboratory. Part of the teaching will be done in one of the companies.

1. Educational goal:

The following are the objectives of the course of Entrepreneurial Management: 1) to acquire the basic knowledge in the field of entrepreneurial management in the modern business environment; 2) to introduce students with the basic determinants and forms of entrepreneurial management; 3) to acquire the basic knowledge and key skills of managing successfully both small and medium sized enterprises, as well as large industrial systems, and 4) to introduce students to management styles in companies.

2. Educational outcomes (acquired knowledge):

Students attending the course and passing the exam are able to: 1) create the preconditions for successful entrepreneurial management in the actual economic environment of both small and large organizations; 2) apply the determinants of entrepreneurial management in organizations; and 3) to implement management styles according to the required level of managerial effectiveness. This course provides students with competencies for managing and improving the organization towards innovating and creating new products and services.

3. Course content/structure:

Introduction to entrepreneurial management; Forms of entrepreneurial management: operative and proactive; Determinants of entrepreneurial management: focus on change, a focus on business opportunities and focus on the organization; Personal factors of entrepreneurs-managers; Managerial/entrepreneurial style of management; Application of styles management; Models and software of managerial/entrepreneurial governance.

4. Teaching methods:

The instruction is provided through lectures, theoretical subject matter with the required number of case studies, as well as through practical exercises aided by computers, consultation, and seminar papers – presentations.

Knowledge evaluation (maximum 100 points)

Precondition courses

1. Educational goal:

Gaining knowledge of modern methods and techniques in the field of human resource management with an emphasis on the practical application of key concepts in business.

2. Educational outcomes (acquired knowledge):

Students will be able to: (1) adopt the current methods and tools in the field of human resource management (2) the application of new skills to master the concepts of human resources, (3) gain knowledge of the business processes of international human resource management (4) analyze and identify professional and organizational profile (5) manage interpersonal relationships using the tools of psychological concepts in a measurable and cost-effective manner (6) identify, analyze and improve business activities based on the knowledge and skills in the field of human resource management.

3. Course content/structure:

Development trends in the management of human resources in the future: challenges for Human Resources in the 21st century, changing nature of work, employment, human resources in the public and private sectors.
International human resource management definitions, settings, international organizational models, cultural differences.
Human resource management in practice: adoption of new skills and tools used in practice, the modern tools of the process of recruiting employees, employee competence (types, frame, for reasons of competence, competency model development), interpersonal relations and intelligence employees (setting, the nature of relationships, trust and organizational relationships)
Psychological contracts: definitions, significance, nature of contract, maintaining a positive agreement.
Organizational Portfolio: diagnosis reference frame of the organization, staff, alignment of organizational and individual needs, organizational development and transformation
Professional identity: the professional game, professional style, talent acquisition, the balance between life and work.

4. Teaching methods:

Teaching includes lectures on the subject, with examples and exercises designed through team discussions, workshops, internet research, case studies.

1. Educational goal:

The subject aims to enable students to understand many basic concepts, processes, and issues that arise when performing empirical studies in most disciplines of management, and thus create a conceptual basis for later studies in facilities that include this type of knowledge.

2. Educational outcomes (acquired knowledge):

Students are trained in-house research design, data collection, data processing, multivariate methods (exploratory factor analysis, EFA, confirmatory factor analysis CFA, structural modeling, SEM, cluster analysis, canonical correlation analysis, the discriminatory analysis, a method of neural networks, data interpretation and preparation report on the research conducted and the use of the software package SPSS, AMOS, LISREL.

3. Course content/structure:

The presentation material is a continuation of the course, its advanced section where students are trained to perform the collection, processing and analysis of data using multivariate procedures that are consistent with the trends of the world's leading journals in the field (in depth). These are the procedures and konfarmitivne exploratory factor analysis, cluster analysis and Structural modeling method. The focus is primarily on logic and above all practice mentioned at the end of the course describes the structure of a standard written report on the investigation. During the course, for illustration shows a large number of (mostly simplified) examples of research in many areas of management.

4. Teaching methods:

Lectures, computer exercises, consultations

Knowledge evaluation (maximum 100 points)

1. Educational goal:

Acquiring specific knowledge in the field of comparative (simultaneous) engineering.

2. Educational outcomes (acquired knowledge):

Ability to deal with scientific and research work in the field.

3. Course content/structure:

Basic concept and history of DFX, Predecessors of the design for excellence, Abilities for assembly and manufacture, Basic idea and necessity of applying DFX, Diverse DFX approaches, Basic principles for DFX, Organization and Management of DFX approach, Procedure for product development, Comparative or simultaneous engineering (SE), Teamwork and cooperation, Evaluation of proposed solutions for improvement, Dimensions of DFX, Design for Assembly (DFA), Design for Manufacture (DFM), Design for Quality (DFQ), Design for Cost Optimization (DFC), Design for reliability, Design for service and maintenance, Design for safety, Design for environment protection, Design for simple usage, Design for fast market introduction, Computer-aided DFX and the integration with CAD, IIS-DFX developed tools in CAD, Tendencies for future development of the DFX approach.

4. Teaching methods:

Lectures. (Mentor and students select one or more modules depending on the size of the module content.) Consultations. Lectures are organized in combined form. The presentation of the theoretical part is followed by the corresponding examples. In addition to lectures there are regular consultations. In study and research, students investigate through scientific journals and other literature independently to upgrade the lectures. In working with the teacher, student is becoming capable for individual writing of a scientific paper.

1. Educational goal:

The application of fundamental, theoretical and methodological, scientific and professional, and professional and applicative knowledge, methods and contemporary knowledge from the magazines from the SCI list in order to solve concrete problems within the courses at Doctoral studies.

2. Educational outcomes (acquired knowledge):

Enabling students to individually connect the contents from the courses at Doctoral studies, apply previously acquired as well as new knowledge for observing the structure of the set problems and its systematic analysis in order to elaborate conclusions on possible directions in its solving. Through individual usage of literature, students broaden their knowledge and utilizing new methods individually and creatively, they use new knowledge in solving the set problems.

3. Course content/structure:

It is formulated individually in accordance with further research. Students read scientific literature, and perform analyses in order to find solutions for a concrete task which is defined by setting the task on the side of the supervisor and other lecturers at Doctoral studies. Theoretical bases present a classification examinations. Students are prepared to take the classification examination.

4. Teaching methods:

Student`s co-supervisor sets the seminar paper task and delivers it to the student. The student has the obligation to elaborate the paper within the set theme defined by the paper task, utilizing the literature proposed by the co-supervisor. During the paper elaboration, the co-supervisor can provide additional instructions to the student direct them to certain literature and additionally direct them towards the elaboration of a quality paper. During the study research work, the student has tutorials with the co-supervisor and course lecturers, and if needed, with other lecturers dealing with the problems in the field of the set paper task. Within the set theme, the student can also perform certain measuring, research, calculations, surveys and other researches, statistic data processing, if it is necessary for the task. After the defence of the paper, the candidate has to pass the oral examination in the field of the passed examinations, in front of a committee. If the examination is

1. Educational goal:

The application of fundamental, theoretical and methodological, scientific and professional, and professional and applicative knowledge and methods in solving concrete problems within the selected field. In this segment of Doctoral dissertation, students investigate the problem, its structure and complexity and on the basis of the performed analyses draw conclusions on possible manner in its solving. Researching the literature, students are introduced to methods attended for creative solving of new tasks and the engineering practice in their solving. The objective of students` activity within this segment of research is to acquire necessary experience through solving complex problems and tasks and recognizing the possibility for applying previously acquired knowledge in practice.

2. Educational outcomes (acquired knowledge):

Enabling students to individually apply previously acquired knowledge from diverse areas already studied in order to observe the structure of the set problem and its systematic analysis for drawing conclusions on possible directions in its solving. Through individual usage of literature, students broaden their knowledge from the selected field and they investigate diverse methods and papers related to the similar fields. Thus, students develop the competence to perform analyses and identify problems within the set theme. Practical application of the acquired knowledge from diverse areas develops in students the ability to overview the place and the role of engineers in the selected field, the demand for cooperation with other professions and the team work.

3. Course content/structure:

It is formulated individually in accordance with the elaboration of the concrete Doctoral dissertation, its complexity and structure. Students read scientific literature, Doctoral dissertations by other students dealing with similar theme; they perform analyses in order to find solutions for a concrete task defined by the task of the Doctoral dissertation.

4. Teaching methods:

The supervisor of the Doctoral dissertation sets the dissertation task and delivers it to the student. The student has the obligation to elaborate the dissertation within the set theme defined by the Doctoral dissertation task, utilizing the literature proposed by the supervisor. During the elaboration of the Doctoral dissertation, the supervisor can provide additional instructions to the student direct them to certain literature and additionally direct them towards the elaboration of a quality Doctoral dissertation. During the study research work, the student has tutorials with the supervisor, and if needed, with other lecturers dealing with the problems in the field of the set dissertation task. Within the set theme, the student can also perform certain measuring, research, calculations, surveys and other researches, statistic data processing, if it is predicted by the task of the Doctoral dissertation.

Precondition courses: None

1. Educational goal:

The continuation of study and research from previous semester. The application of fundamental, theoretical and methodological, scientific and professional, and professional and applicative knowledge and methods in solving concrete problems within the selected field. In this segment of Doctoral dissertation, students investigate the problem, its structure and complexity and on the basis of the performed analyses draw conclusions on possible manner in its solving. Researching the literature, students are introduced to methods attended for creative solving of new tasks and the engineering practice in their solving. The objective of students` activity within this segment of research is to acquire necessary experience through solving complex problems and tasks and recognizing the possibility for applying previously acquired knowledge in practice.

2. Educational outcomes (acquired knowledge):

Enabling students to individually apply previously acquired knowledge from diverse areas already studied in order to observe the structure of the set problem and its systematic analysis for drawing conclusions on possible directions in its solving. Through individual usage of literature, students broaden their knowledge from the selected field and they investigate diverse methods and papers related to the similar fields. Thus, students develop the competence to perform analyses and identify problems within the set theme. Practical application of the acquired knowledge from diverse areas develops in students the ability to overview the place and the role of engineers in the selected field, the demand for cooperation with other professions and the team work.

3. Course content/structure:

It is formulated individually in accordance with the elaboration of the concrete Doctoral dissertation, its complexity and structure. Students read scientific literature, Doctoral dissertations by other students dealing with similar theme; they perform analyses in order to find solutions for a concrete task defined by the task of the Doctoral dissertation.

4. Teaching methods:

The supervisor of the Doctoral dissertation sets the dissertation task and delivers it to the student. The student has the obligation to elaborate the dissertation within the set theme defined by the Doctoral dissertation task, utilizing the literature proposed by the supervisor. During the elaboration of the Doctoral dissertation, the supervisor can provide additional instructions to the student direct them to certain literature and additionally direct them towards the elaboration of a quality Doctoral dissertation. During the study research work, the student has tutorials with the supervisor, and if needed, with other lecturers dealing with the problems in the field of the set dissertation task. Within the set theme, the student can also perform certain measuring, research, calculations, surveys and other researches, statistic data processing, if it is predicted by the task of the Doctoral dissertation.

Knowledge evaluation (maximum 100 points)

Precondition courses: None

1. Educational goal:

Acquiring knowledge about structure and form of writing the dissertation report after analysis, and other activities carried out within the assigned theme of Doctoral dissertation. By writing the Doctoral dissertation, students gain experience in writing papers within which it is necessary to describe the problem, implement methods and procedures and obtained results, as well as to give new scientific contribution to the science development and to the application of the scientific research in practice. In addition, the objective of writing and defense of the Doctoral dissertation is to develop student skills for independent paper preparation in a suitable form for the purpose of public presentation, as well as to respond to comments and questions related to the given topic.

2. Educational outcomes (acquired knowledge):

Training students for a systematic approach in solving the given problems, carrying out analyses, applying knowledge and accepting knowledge from other areas in order to find creative solutions for a given problem. Through independent studying and solving tasks in a given topic, they acquire the knowledge about the complexity of the problems in the field of their profession. Through elaboration of Doctoral dissertation, students gain certain experiences that can be applied in practice when solving problems in the field of their profession. The student acquires necessary experience on how to present the results of independent or team work in practice by preparing the results for public defense, by public defense, and by answering questions and complaints of the Commission.

3. Course content/structure:

It is individually formed in accordance with the needs and the field covered by a given Doctoral dissertation. In agreement with a mentor, a student makes the Doctoral dissertation in a written form in accordance with the rules provided by the Faculty of Technical Sciences. The student prepares and defends the written Doctoral dissertation in public, in agreement with the mentor and in accordance with the prescribed rules and procedures.

4. Teaching methods:

During the elaboration of the Doctoral dissertation, the student consults with his/her mentor, and if necessary with other teachers dealing within a sphere of the Doctoral dissertation. The student writes the Dcotoral dissertation, and submits the bound copies to the Commission upon the approval of the Commission for assessment and defense. The Defense of the Doctoral dissertation is performed in public, and after the presentation, the student is obliged to orally answer the questions and comments.

Knowledge evaluation (maximum 100 points)					
Pre-examination obligations	Mandatory	Points	Final exam	Mandatory	Points
Writing the PhD thesis	Yes	50.00	PhD thesis defence	Yes	50.00

Standard 06. Programme Quality, Contemporaneity and International Compliance

The study programme is consistent with the modern scientific trends and state of the profession in the world, and is comparable with similar programs at foreign universities.
The study programme as conceptualized is thorough and comprehensive, providing students with the latest scientific and professional knowledge in this area and following new achievements in science.
The study programme of Industrial Engineering / Egineering Management is comparable and complies with several doctorial academic studies both throughout the world and in Europe.
1. Northwestern University, Evanston, IL, USA
http://www.iems.northwestern.edu/images/pdf/MajorMinor.pdf
2. Helsinki University of Technology, Helsinki, Finland
http://www.tuta.hut.fi/studies/postgraduates/pstgrGUIDE_dr1995.pdf
3. Koç University, Istanbul, Turkey
http://www.iems.northwestern.edu/images/PDF/CoreTopics.pdf
4. Groupe des Ecoles des Mines, Paris, Sain-Etienne & Nantes, France
http://www.gemtech.fr/66919641/1/fiche___pagelibre/#4

http://kontakt.tu-hamburg.de/en/gen/fsp.html
https://engineering.purdue.edu/IE/Academics/PhD
Both formally and structurally, the study programme is consistent with the approved subject-specific standards of accreditation and complies with European standards in terms of enrollment, length of study, conditions of transition to the next year, graduation and type of study.

Standard 07. Student Enrollment

Faculty of Technical Sciences announces an admission of candidates to the program of doctoral studies Industrial Engineering / Engineering Management in accordance with social needs, their free resources and approved number of students in the accreditation process. The number of students who will be enrolled and funding of their studies (budget or self-financing) is defined each year by a Scientific Council of faculty.

For admission can apply Candidates who have completed the corresponding Masters or graduate studies and whose previous studies evaluated a total of at least 300 ECTS, which is defined in the Regulations on student enrollment in courses.

Candidates who, in the opinion of the Commission, have completed an appropriate program of study are eligible to enroll in doctoral studies. Commission for the registration shall decide whether candidates are eligible to take entrance examination enrollment. If Quality Commission decision on taking the classification exam, the candidates take this the exam which addresses to testing knowledge of the program of study. If the number of candidates is less than the number of accredited students and the Commission finds that the candidates have completed an appropriate program of study, the Commission may decide that it is not necessary to organize the classification exam.
The final ranking of candidates for admission is based on success in previous studies, the duration of the study and achieved success on the entrance exam, as defined in Regulation on student enrollment in courses.
The Commission, in accordance with Regulation on student enrollment in degree programs, has the right to approve the registration of candidates who have not completed the corresponding Masters or postgraduate studies which are worth a minimum of 300 ECTS, and only in the event that vacancies remain after the registration of all candidates who meet the requirements Competition set (corresponding previous studies, passed the classification exam). Candidates with the professional judgment of the Commission, have not completed the relevant study program of undergraduate studies may be granted admission if they pass the entrance exam.
Members of the Council of doctoral studies are at the same time members of the Commission for the registration of doctoral studies in accordance with Regulation on student enrollment in degree programs.

Standard 08. Student Evaluation and Progress

The final grade for each of the courses of this programme is formed by continuous monitoring of the students` work and the results during the school year and the final exam.
The student masters the programme by taking exams, earning thereby a certain number of ECTS credits, in accordance with the study programme. Each individual course in this programme carries a certain number of ECTS credits earned by the student when successfully passing the exam.
The number of ECTS credits is identified based on the student`s workload in mastering a particular course and by applying a uniform methodology of the Faculty of Technical Sciences for all study programs. The success of students in mastering a particular course is continuously monitored during the class and is expressed in credits. The maximum number of credits a student can earn on the course is 100.
The student earns credits on the course by working during the classes, and by satisfying pre-exam requirements. The minimum and maximum number of credits a student can achieve by satisfying pre-exam requirements is 30 and 70, respectively.
Each course from the curriculum has a clear and published way of earning credits. The way of earning credits during the classes includes a number of credits that students earn from each individual type of activity in the classroom or by satisfying pre-exam requirements.
The total success of the student on the course is expressed by grades from 5 (failed) to 10 (excellent). The student`s grade is based on the total number of credits earned by satisfying the pre-exam requirements and on the quality of acquired knowledge and skills.
Studying the degree program is realized as follows:
At the enrollment, the Head of the study programme (study group) appoints each student a mentor from among professors who will lead them until a mentor is choosen.
At the end of the semester, the mentor submits a report to the Head of the study (group) on student`s work during the research and his results.
Requirements for enrolling the second year of the study (third semester) is defined by Regulation.
The right to take the qualifying exam for the preparation and defense of the doctoral dissertation (research work on theoretical bases of doctoral dissertation) is gained by the student who has certified the second year of study and passed all the exams foreseen by the study programme.
Students who do not meet the requirement for taking the exam from the theoretical basis of the doctoral dissertation have the possibility to continue their studies at specialist academic studies with the exams being recognized.
Research work on the theoretical bases of the doctoral dissertation is a qualifying exam for the doctoral dissertation. Theoretical bases are taken as an exam (written and / or oral) by fields (questions) from at least three courses of the study program. The list of fields (questions) from which the qualifying exam is taken is submitted to the candidate by the Head of the doctoral study program within 14 days upon the request. The qualifying exam is taken before a committee of at least three members, appointed by the Manager of doctoral studies upon the proposal submitted by the Committee for quality of the study programme. Upon the request of students, the theoretical bases of doctoral dissertation can be taken not earlier than 30 days and not later than 12 months from taking the final exam.
Examinations for doctoral studies can be taken up to three times.
The final part of doctoral studies is the preparation and defense of the doctoral thesis.
Exams for doctoral studies can be taken up to three times.
The final part of doctoral studies is the creation and defense of a thesis.

Standard 09. Teaching Staff

For realization of the study program of Industrial Engineering / Engineering Management the teaching staff is provided with the necessary professional and academic qualifications, as evidenced by the list of papers and data on participation in national and international research projects. The competence of lecturers is based on scientific papers published in international journals, with at least one paper being published or accepted for publication in a SCI list journal, scientific papers published in national journals, papers published in proceedings of international conferences, monographs, patents, textbooks, new products or significantly improved existing products.

The mentor has at least five scientific papers published or accepted for publication in scientific journals in a given area. The mentor can not lead simultaneously more than five doctoral students. The selection of a mentor is defined so that mentor must have at least 5 papers published in SCI journals.

The number of professors meet the needs of the curriculum and depend on the number of courses and number of classes on these courses. The total number of lecturers is sufficient to cover the total number of classes at the study programme(lectures, consultations, practical work, ...). The minimum number of full-time lecturers participating in a given academic program is at least five.
Scientific and professional qualifications of the teaching staff match the educational and scientific field and the level of their responsibilities. Each lecturer has at least 10 references from specific scientific or technical fields of teaching in the program of study.
All data on lecturers and associates (CV, elections for the position, references) are available to the public.

Study Programme Accreditation - PhD Studies

DOCTORAL ACADEMIC STUDIES — Industrial Engineering / Engineering Management

Science, arts and professional qualifications

Name and last name:	Palčič -. Iztok
Academic title:	Associate Professor
Name of the institution where the teacher works full time and starting date:	-
Scientific or art field:	Production Systems, Organization and Management

Academic carieer	Year	Institution	Field
Academic title election:	2009	Faculty of Technical Sciences - Novi Sad	Production Systems, Organization and Management
PhD thesis	2004	Faculty of Mechanical Engineering - Maribor	Production Systems, Organization and Management
Magister thesis	2002	Faculty of Mechanical Engineering - Maribor	Mechanical Engineering
Bachelor's thesis	1999	Faculty of Mechanical Engineering - Maribor	Mechanical Engineering

List of courses being held by the teacher in the accredited study programmes

	ID	Course name	Study programme name, study type
1.	IM1046	Structural and Development Projects	(I20) Engineering Management, Undergraduate Academic Studies
2.	IM1317	Project Procurement Management	(I20) Engineering Management, Undergraduate Academic Studies
3.	IM1821	Managing Media Projects	(I20) Engineering Management, Undergraduate Academic Studies
4.	HDOK4S	Selected chapters from automation of work processes	(I12) Industrial Engineering, Specialised Academic Studies
5.	IMDS59	Project approach in Effective Systems	(I12) Industrial Engineering, Specialised Academic Studies (I22) Engineering Management, Specialised Academic Studies
6.	MBA413	Knowledge Systems and Project Management	(I20) Engineering Management, Specialised Professional Studies (IB0) Engineering Management - MBA, Specialised Professional Studies
7.	PLM05	Management of PLM Projects	(I1U) Industrial Engineering - Product Lifecycle Management and Development, Master Academic Studies
8.	IM2101	Intelligent Enterprising and Effective Management	(M50) Energy Management, Master Academic Studies (I20) Engineering Management, Master Academic Studies
9.	IM2107	SAP Enterprise systems	(M50) Energy Management, Master Academic Studies (I20) Engineering Management, Master Academic Studies
10.	IM2314	Program and Portfolio management	(I20) Engineering Management, Master Academic Studies
11.	HDOK-4	Selected Chapters in Production Process Automation	(H00) Mechatronics, Doctoral Academic Studies (I20) Industrial Engineering / Engineering Management, Doctoral Academic Studies
12.	HDOKL4	Selected chapters from automation of work processes	(H00) Mechatronics, Doctoral Academic Studies
13.	IMDR59	Project Approach in Effective Systems	(I20) Industrial Engineering / Engineering Management, Doctoral Academic Studies

Standard 10. Organizational and Material Resources

To perform the study programme, the adequate human, spatial, technical and technological, library and other resources suitable to the study programme features and predicted students` number are provided.
To perform the study programme, the adequate space for lecturing is provided, as well as the adequate laboratory space necessary for the experimental work and the equipment based on contemporary information and communication technologies. Lectures are held in amphitheatres, classrooms and specialized laboratories.
Faculty provides the usage of the library fund from its own or other sources (books, monographs, scientific magazines, other periodicals) in the amount necessary for the Doctoral study programme. Doctoral study students have the access to databases necessary for Doctoral dissertation elaboration and scientific and research work.
The library possesses more than 100 library units relevant for the performance of the study programme. All courses from the study programme have adequate textbooks, devices and supplementary equipment available on time and in a satisfactory number for the normal teaching process. There is also adequate information support.
Faculty has the library and the study room and provides a seat for each student in amphitheatres, classrooms and laboratories.
Faculty has a short-term and a long-term plan and the budget for the realization of scientific and research work.
Means for the realization of Doctoral studies, besides the ones provided by the resource ministries, are also provided in cooperation with other higher education institutions, accredited scientific institutions and international organizations.
Faculty provides students to utilize equipment or have access to necessary and adequate equipment in the possession of the Faculty, for scientific and research work.
Faculty provides students to utilize equipment or have access to the equipment necessary for scientific and research work on the basis of contracts on cooperation with other appropriate institutions.

Standard 11. Quality Control

Estimation of the study programme quality is elaborated regularly and systematically via self-evaluation and external quality control. One should place an emphasis on the multi-decade practice of students` surveys.
Study programme quality control is elaborated in the following manners:
- Surveying students at final lecture from the given course.
- Surveying students on the quality of the study programme and logistic support to the studies in the event of awarding the Diploma. Also, the studying comfort (classroom cleanness and tidiness) is evaluated there.
- Surveying students during the confirmation on completing a year of studies. Then students evaluate the logistic support to the studies.
- Surveying students on enrolling each year of studies. Then students evaluate the study programme at the year they completed in the prior academic year.
- Surveying the teaching and non-teaching staff on the quality of the study programme and the logistic support to the studies. This survey evaluates the work of the Dean`s office, Registrar`s office, library, and other services at the Faculty.

To monitor the quality of the study programme, there is a committee whose members are Doctoral Studies Council (composed of Faculty of Technical Science professors)two members of non-faculty stuff (administrative officer), together with a one student.
Additional quality is obtained by the obligatory scientific production of candidates. Prior to beginning the defence of the Doctoral dissertation, each candidate is obliged to publish at least one paper in the magazine from the SCI list.
